Actual Instances of Dual Personalities—I*

Cases in Real Life That Rival the Wildest Fiction

By Edward Tyson Reichert, M.D., Sc.D., Professor of Physiology in the University of Pennsylvania

THE noted English author, Mr. H. G. Wells, was asked, "What is the first step toward literary production?" and he is accredited with the reply: "It is imperative, if you wish to write with any power or freshness at all, that you must utterly ruin your digestion." Perhaps in such a light the originality of the stories of "Dr. Jekyll and Mr. Hyde" and "The Case of Becky" may suggest to some of you the outpourings of abnormal minds, but we find in the histories of the lives of some who have lived before or with us abundant inspiration for such fiction.

When we speak of an individual's personality we have reference to the sum or totality of his mental traits, which traits are expressions of correlations of the past with the present, and not only of his individual past, but also of the lives of ancestral generations which have left their impression on his mental processes. Personality is a manifestation of an extremely complex aggregate of interassociated and interacting mental states—a combination that is so plastic that one or more of the components may become suppressed or exaggerated, and thus transiently or permanently impart to the individual mental characters that are more or less at variance with his recognized identity.

All are aware of the transitional character of our personalities in our every-day lives, as is expressed especially by our variable moods; by the duplicity of personality of the habitual one-day saint and six-day sinner; by the ease with which the actor assumes different personalities, associating with each such traits as characterize the subject; and by the changes brought about by intoxicants—the quiet, kind, loving, moral, cultured man, becoming quarrelsome, brutal, lewd, profane, and utterly lacking in the high ideals that characterize his normal life. We know too that in somnambulism, delirium and certain hysterical states the individual may exhibit mental traits which in many respects are markedly or wholly different from those which typify his normal life; that hasheesh and certain other drugs may produce in the subject a delusion of an existence of a double personality, that is, a sense of having two mental lives which may hold communication; that in certain forms of insanity the individual has the belief of a dual mental and physical existence, even becoming obsessed with the delusion that he is not himself but his double; and that the mental life of normal, hypnotic and narcotic sleep is usually quite different from that of the waking state. But none of these instances is to be included in the category of dual personality because in each there is merely a single personality that has become modified in normal or abnormal ways, whereas in cases of dual personality there are two mental individuals belonging to one body, both sane, each having self-consciousness, and each having its own characteristic mental life.

There can be no question of a close relationship between the psychic states of somnambulism, hysteria, delirium and insanity with those of dual personalities, and it may not always be possible to definitely differentiate them. Where insanity begins and sanity ends no one knows—who can tell whether or not certain people are sane or insane? Similarly, where modifications of a single personality end and dual personalities begin no one can say, yet in both instances there are well-defined types that are so definitely characteristic that we can declare positively that there is one or the other. It is such types that must be studied at the outstart if we are to have clear conceptions of class distinctions and understand the psychology of these extraordinarily interesting cases of two different minds belonging to one body.

Typical cases of dual personality are characterized by the existence of two distinct, sane, self-conscious mental lives belonging to one body. The change from one personality to another is usually abrupt, without obvious cause, and commonly following a period of loss of consciousness, usually sleep, which commonly is long and profound. Upon the return of consciousness there exists a partial or complete loss of memory of the knowledge that particularized the individual's life, this loss being associated with a change of character, so that the subject is to all intent and purposes another mental individual, having a different memory, will, disposition, intellectual powers and habits of mind and body. The acquired personality or secondary state may have no recognition of the existence of the primary or normal state, or *vice versa*; its mental and physical lives may be so entirely different from those of normal life that if reversion occurs to the primary state his secondary state may, as it were, be completely blotted out, so that mental existence is resumed where it ceased when the secondary state appeared, the subject having no knowledge of his life in the interim. In some instances there occurs repeated alternation of the two personalities, and in such cases one personality may at once, or in the course of time, recognize the existence of the other, the subject becoming conscious of a dual mental existence, eventually blending the two, or adopting one or the other permanently, and not infrequently the secondary, or supposed secondary, state. Sometimes there appear multiple personalities, that is, as many as ten or more personalities may be developed, one succeeding another, each differing from the others, each being as characteristic as though the individual had been as many times reborn. And so one might go on indexing these varied and uncanny manifestations of mental life which seem more like freaks and monstrosities of the imagination than actualities of life. Perhaps as many as forty cases of dual and multiple personality have been reported, some of which have been republished time and again, yet they are almost unknown even to the medical profession. Undoubtedly a very large number have existed, and many of the unfortunate subjects found lodgment in insane asylums and prisons.

* A lecture delivered at the University of Pennsylvania, December 19th.

Turning our attention now for a few minutes to fiction, and first to Robert Louis Stevenson's story of Dr. Jekyll and Mr. Hyde, Dr. Jekyll is described as a large, well-made, smooth and handsome-faced man of fifty, with perhaps something of a slyish cast, but with every mark of capacity and kindness, and who cherished sincere and warm affections. He was a connoisseur, inclined by nature to industry, and fond of the respect of the wise and good. The worst of his faults was a certain impatient gayety of disposition, such as has made the happiness of many, but such as he could not reconcile with his imperious desire to carry his head high and wear a more than commonly grave countenance before the public. Hence, while he indulged he concealed his pleasures, hiding them with an almost morbid sense of shame, and standing committed to a profound duplicity of life. He saw that two natures contended in the field of consciousness and he conceived of the separation of these natures by taking a drug, and of recombining them by an antidote.

Upon taking the potion, agonies were caused which swiftly subsided, and as if out of a great sickness he came to himself in the form of Mr Hyde, a man tenfold more wicked than his primary self and sold a slave to his original evil. As Mr. Hyde he was dwarfish and gave the impression of deformity without namable malformation. He had a displeasing smile and bore himself with a sort of murderous mixture of timidity and boldness. He spoke in a husky, whispering, and somewhat broken voice, and his manner aroused disgust, loathing, and fear. He seemed hardly human and was inherently malign and malicious, taking pleasure in the infliction of every degree of torture. He had the name of Satan written on his face. Mr. Hyde, drinking the antidote, cried, reeled, staggered, clutched at the table, staring with injected eyes and gasping with open mouth, pale and shaken and half fainting, was transformed to Dr. Jekyll. The two natures had memory in common, but all other faculties were most unequally shared between them.

Transitions from one state to the other were frequent, and in time Dr. Jekyll, like those of us in everyday life who habitually give way to evil inclinations, lost hold, as it were, of his original and better self, and became slowly incorporated with his secondary or worse self in the form of Mr. Hyde. He soon came to a realization that he had to choose between the two, and choosing the better, he for two months was Dr. Jekyll. Then, in an hour of moral weakness, he again swallowed the transforming potion, and instantly the spirit of hell awoke and raged in him, and again was he the moral monster, Mr. Hyde.

"The Case of Becky," while presenting certain features in common with those of Dr. Jekyll and Mr. Hyde, is in its manifestations of the secondary state and in certain other respects quite different. The story of Dr. Jekyll and Mr. Hyde belongs to the category of drug fiends we read of from time to time in the daily press; but "The Case of Becky" is one of dual personality, and the conceptions of the author are well founded in histories of cases in life which are even more weird and interesting, and seemingly improbable.

In normal life the person of Becky was known as Dorothy. Dorothy, it will be recalled, was the stepdaughter of an unscrupulous, itinerant hypnotist. She was made by him a hypnotic subject, and grew up amid surroundings such as would naturally tend to develop in a very sensitive girl abnormal mental states. She in time fled in terror from her degenerate and conscienceless stepfather, to be found after some years in a sanitarium, where we are made familiar with her dual lives. As Dorothy, she was a highly sensitive, charming and lovable young woman; sweet tempered, fond of reading, and with exemplary habits of mind and body. At times upon awaking from a short sleep she would exhibit a personality which was the very antithesis of the normal. In this state she was known as Becky. She was quarrelsome, disagreeable, used coarse language, was profane, tore her clothing, and took great delight in annoying those about her, and played all sorts of disagreeable tricks upon her primary self, which appeared to her as the person of another individual, hiding and destroying things which she imagined belonged to this hated person.

Mr. Belasco, in the staging of "The Case of Becky," showed remarkable skill. Dorothy was a very impressionable girl who, because of abusive treatment and repeated subjection to hypnosis by her stepfather, had her mind so peculiarly affected as to become a victim of self-hypnosis and to lead to the development of a second personality entirely different from her normal. After the appearance of the second personality an alternation of the primary and secondary states took place for years, until finally, under the care of an expert neurologist, she was, through hypnosis restored to her normal self. Such cause, effect and cure are wholly in accord with the facts of science, although perhaps exceedingly few of the audience, and very few critics, looked upon them as being otherwise than entirely imaginative.

What seemed to be the most vulnerable feature of the presentation was Dorothy's consciousness of the presence of her stepfather in some way other than by her ordinary senses—in some occult manner, such as by telepathy, that is, by an influence of one mind over another at a distance by other than the normal channels of communication. But this very point, seemingly small and unimportant to the lay mind, was not overlooked by so skillful a stage craftsman. Those who followed the play with discernment will recall that at a moment before Dorothy appeared on the stage in a self-hypnotic state her stepfather, who was unseen at the time, had coughed loudly and in a strikingly peculiar way—a cough which we are supposed to understand was heard throughout the sanitarium. It was this cough which was intimately related to the horrors of her girlhood, though not consciously recognized by Dorothy, that so affected her peculiarly sensitive and abnormal mind as to throw her into hypnosis. In this condition she was en rapport with her stepfather, extremely sensitive to his presence, and almost wholly submissive to his will. Even in the hypnotic state she has some consciousness of her well-nigh helplessness and the perils that encompassed her in the presence of her stepfather. To dissipate the tendency to self-hypnosis and prevent the recurrence of the secondary state by hypnotic suggestion, in accordance with the play, may seem to be visionary, yet it is entirely consistent with the facts of science. The presentation of the dual character was remarkably true to life.

Turning now from fiction to strange stories from life, we find that the essential features of "The Case of Becky" have their counterpart in the history of the case of Miss Beauchamp, which was published by Dr. Morton Prince ("The Dissociation of Personality," 1906). The subject was a person in whom three personalities spontaneously developed, each being distinctly different from the others in trains of thought, views, ideals, temperament, acquisitions, tastes, habits, experiences and memories. Only one of the three had any inherent knowledge of the others, and the other two had no knowledge of each other or of the first except such as had in time been obtained by inference or by information from other people. Suddenly we find one personality vanishes and another appears in kaleidoscopic succession, each being ignorant of what was said or done or where she was while in the immediately preceding personality. For six years these three personalities played a remarkable and almost unbelievable comedy of errors, making their entrances and exits in a most inexplicable way, each for a time playing her part, each being as individualized mentally and physically as though there were three persons having quite different personalities.

Miss Beauchamp is described as having been a nervous, impressionable child, given to day-dreaming, living in

her imagination, unduly influenced by her imagination, living in a land of idealism, and seeing people not as they are but as she imagined them to be, and lacking in true conceptions of her environments She was intellectually keen and fond of books, and she idolized her mother, who, however, was devoid of affection for her, the effect of which was to make her morbidly reticent and live within herself and her imagination. When eighteen years of age a nervous shock played the principal role in the development of the remarkable personalities that for some years encompassed her life At twenty-three she was a college student, ambitious, over-conscientious, mentally and morally stubborn, very nervous, a neurasthenic of an extreme type, and a continual sufferer mentally and physically, becoming worse, and ultimately unfitting her for work

In the course of time two personalities developed which came to be distinguished as Sally and the Idiot The three personalities (Miss Beauchamp, Sally and the Idiot) were so different as to suggest the designations The Saint, The Woman and The Devil

Inasmuch as Miss Beauchamp was a physical wreck, it might naturally be assumed that her bodily ailments would be carried into her other states, so that notwithstanding great changes in mental traits her bodily traits would continue the same But this did not occur, thus showing in an extraordinarily impressive way the potent influences of the mind over the body While Miss Beauchamp was always ill, always suffering, always physically weak and incapable of more than very little physical and mental exertion, the Idiot showed a markedly lessened neurasthenia and was capable of physical and mental exertion much beyond the powers of Miss Beauchamp, yet with distinctly less capacity than Sally As Sally, the Devil, she was a stranger to illness and had remarkable physical endurance knowing neither fatigue nor pain While in the state of Sally she would take long walks, far beyond the physical strength of Miss Beauchamp, and then suddenly Sally would vanish and the body be returned to Miss Beauchamp, who would come to herself in a state of utter exhaustion notwithstanding that only a few moments before, as Sally, there was physical vigor

Miss Beauchamp and the Devil in their physiological and moral tastes, moral characteristics and acquisitions were almost wholly antipodal The kinds of food and drink liked by one were disliked by the other Miss Beauchamp's appetite was poor, she cared little for the pleasures of the table never used vinegar or oil, and was very fond of ice cream and broths, etc The Devil had a good appetite, enjoyed the table, used freely vinegar and oil, never ate ice cream or broths, etc Miss Beauchamp wore her hair low and her clothing loose and was fond of church and devotional books The Devil wore her hair high and her clothing tight, and never voluntarily entered church or read devotional books Miss Beauchamp was patient considerate of others, amiable, hated sewing, and was very fond of children The Devil was most impatient, most inconsiderate, unamiable, given to rages of violent temper, liked sewing and looked upon children as a great nuisance Acquisitions of Miss Beauchamp were often not possessed by the Devil and those of the latter not often by Miss Beauchamp And so in very many ways one personality was the antithesis of the other

Sally is described as having a character trains of thought, memories, perceptions, acquisitions and mental traits generally which were quite different from those of Miss Beauchamp Sally claimed that she knows what Miss Beauchamp thinks, says, writes and does, sees what she sees at the time, and not as knowledge afterwards acquired Curiously enough, while Miss Beauchamp could hide absolutely nothing from Sally she was absolutely without knowledge of the existence of Sally, and Sally, while recognizing the existence, thoughts and so on of Miss Beauchamp, did not associate Miss Beauchamp with herself or her body, but imagined her to be another individual Sally had a jealous hatred of Miss Beauchamp, and remarkable and almost incredible were the pranks, torments and terror to which Miss Beauchamp was subjected The personalities of Miss Beauchamp and Sally frequently alternated A favorite form of Sally's amusement was to suddenly vanish and restore the body to Miss Beauchamp under conditions that would give rise to great mental and physical suffering Sally would write most annoying letters to Miss Beauchamp and she had a most subtle way of stating just enough to cause Miss Beauchamp's imagination to run riot and to fancy all sorts of things, and generally to create a state of mind full of apprehension or even terror Sally would make engagements which she knew Miss Beauchamp could not keep and often Miss Beauchamp would awake to find that she had unknowingly done something entirely different from that which she had contemplated Miss Beauchamp's promises were broken and engagements were made which were objectionable, or even of such a character as she could not in honor keep Sally would write letters exposing the private affairs of Miss Beauchamp, and by distorting exaggerating and deliberately lying she caused the keenest sense of mortification and increased the illness of Miss Beauchamp by the intense anxiety

Sally took advantage of Miss Beauchamp's carelessness about the care of money and many were the torments to which the latter were subjected One day Miss Beauchamp was sorely worried over the mysterious disappearance of some money Sally had hidden it and written a note to Miss Beauchamp, which was received a day later, telling Miss Beauchamp that she was too negligent and incapable of taking proper care of money, and that she would accordingly be put on an allowance of ten cents a day with which to amuse herself

For some time thereafter Sally doled out sums of two five or ten cents and then would vanish giving back the body to Miss Beauchamp

For two years this extraordinary and almost incredible play of comedy farce and drama of different personalities in one body went on in alternation

Miss Beauchamp was repeatedly hypnotized by Dr Prince and in the course of time there developed a half-hypnotic state in which there occurred a personality different from the other three She in this state had a full knowledge of the events of the past six years She now seemed to be without the morbid idealism and impressionability so strongly marked in the personality of Miss Beauchamp, and was also without the melancholy sadness and weariness and was less nervous and humble She was light-hearted natural and physically strong and possessed greater spontaneity and intellectual grasp This personality appeared to be the fused personalities of Miss Beauchamp and the Devil a personality that had lost the morbid emotional idealism of the former and the impishness, temper and willfulness of the latter

Naturally the question arises as to which, if any, of these personalities is to be regarded as the real Miss Beauchamp Dr Prince answered this question by showing the real Miss Beauchamp is not the Miss Beauchamp we met at the beginning of our recital, but the fused personalities of Miss Beauchamp and the Idiot he brought about and rendered permanent by hypnosis The personality of Miss Beauchamp as we first knew her was like the personalities of Sally and the Idiot, a dissociated or detached mental state, the other mental states being for the time latent or submerged What became of Sally? The mental state represented by Sally seems to have been a subconscious state that became dominant because of the splitting of the primary self into two parts one part becoming suppressed The union of the personalities of Miss Beauchamp and the Idiot gave rise to a personality of such potentiality that the personality represented by Sally was submerged in subconsciousness The personality of the real Miss Beauchamp after a period of vacillation had continuous existence, and Miss Beauchamp was thereafter a mentally and physically strong individual

In the case of Miss Beauchamp, it will be recalled that while Sally had full knowledge of Miss Beauchamp and the Idiot, the Idiot had only a scrappy knowledge of Miss Beauchamp and no knowledge whatsoever of the existence of either Sally or the Idiot In the case about to be referred to, the secondary personality, unlike Sally, had no knowledge of the primary state, nor had the primary state any knowledge of the secondary The secondary personality curiously enough, played pranks similar to those of Sally, but not upon her own person

(*To be continued*)

Odessa, the Grain Port of Russia

Odessa is one of the most important seaports of Russia ranking, by reason of its population and its foreign trade, after Petrograd Moscow and Warsaw Since it was founded in 1794 near the ruins of a Turkish fort that fell into Russian hands in 1789 it has rapidly become the intellectual and commercial capital of what is called New Russia It is the principal export town for the extensive grain growing districts of South Russia, the See of an Archbishop of the Greek Orthodox Church the center of a fine university and the headquarters of the Seventh Army Corps

The port lies on the shore of the Black Sea about midway between the estuaries of the Dniester and the Dnieper, 967 miles from Moscow and 351 from Kieff The city is built facing the sea, on low cliffs seamed with deep ravines and hollowed out by galleries in the soft rock, in which thousands of the poorest inhabitants live But above this are fine broad tree lined streets and squares bordered with handsome public buildings and mansions in the Italian style, and good shops Besides the cathedral, there are dozens of other churches, a fine opera house, and the Palais Royal, which, with its gardens and park, is a favorite place of resort A magnificent flight of granite steps leads from the Richelieu monument to the harbors, and the shore is lined with granaries, some of which look like palaces.

The bay of Odessa, which has an area of fourteen square miles, was a dangerous anchorage, on account of its exposure to easterly winds, until the harbors within it, six in number, protected by moles and breakwaters were constructed Besides these, there are the harbor of the Russian Company for Navigation and Commerce, and the petroleum harbor These harbors are frozen for a few days only in winter, but navigation is rarely interrupted for more than sixteen days at the most

The population has steadily increased from 8,150 in 1798 to about 480,000 at the present day The total exports were valued some time ago at about $65,000,000 annually and the imports at about $40,000,000, about 8½ per cent of all the imports into Russia Grain and particularly wheat is the chief article of export Petroleum is also an important export at the present time The principal imports are raw cotton iron agricultural machinery coal chemicals jute copra and lead Well over 1 200 vessels of some 1 750 000 tonnage enter the port every year and of these about 700 with a tonnage of 1 250 000 are British—*The Daily Telegraph*

Translucent Glass Bricks

At a recent meeting of the Illuminating Engineers Society one of the speakers made a novel but eminently practical suggestion in regard to the interior lighting of buildings His remarks were as follows

Not long since a resident owner called my attention to the fact that the front rooms of his home were in day time the darkest ones in the house notwithstanding the fact that these rooms were the most used and the most important The darkness was caused there—and in fact will be caused in any average residence by the shielding effect of a large porch and overhanging eaves This is a very common condition and it seems peculiar to me that use has not been made of prism plate glass, or ribbed sheets in the form of skylights set in the veranda roof to direct the daylight against the face of the building and into the windows Glass with a smooth upper side and with prisms on its lower face parallel to the building would direct considerably more light into these front rooms than is found at present Going a little further it seems reasonable to me that use could be made of translucent glass brick or glass blocks in the actual construction of a building Such blocks could readily be made of a glass of pleasing color tints, impervious to weather and it is conceivable how many beautiful effects could be worked into spaces between pilasters, around domes, friezes, etc Many architects do not want to have the exterior of a building made characterless by the use of many windows. Glass brick, tinted the color of stone, would offer a solution of such a problem."

Preventing Soil Erosion

Soil erosion is doing immense damage constantly and few people know how to apply preventive measures In the annual report of the Bureau of Soils of the Department of Agriculture a simple method of handling one class of erosions is described This is the case where the soil is being washed away in gullies and the remedy is to build a dam across the incipient gully through which a sewer pipe is passed connecting with an upright pipe situated at the upper side of the dam The hollow formed by the dam will fill with water in flood conditions until the top of the upright pipe is reached when the excess of water runs off quietly into the next field or into another impounding space below The cutting current of the draining water is stopped and the sediment carried by it settles above the dam thus tending to repair the damage previously done A suitable tile drain located under the dam will dispose of the water impounded below the opening of the upright pipe

A Valuable Sub-Tropical Hay Grass

At the third International Congress of Tropical Agriculture attention was called to a valuable species of grass that has been introduced into South Africa with remarkable success This is known as Teff (*Eragrostis abassinica*) and is an annual hay grass, particularly suitable as a summer catch-crop and a smother-crop for weeds, owing to its rapid growth when weather conditions are at all favorable It gives a heavy yield of hay of fine quality and high nutritive value more nearly resembling English meadow hay than any other hay grass grown in South Africa If sown with the early spring rains it has been possible to cut three crops of hay in the season, giving 2½ to 3 tons per acre, and to obtain autumn grazing from the aftermath The introduction of Teff grass into South Africa has raised many small farmers struggling for a living to positions of comparative comfort and independence They are unanimously agreed that this introduction alone has repaid over and over again the whole cost of the Division of Botany of the Department of Agriculture from its inception to date

Native pearl fishers at work on a bank

An inspector about to descend in a diving dress

The Pearl Fisheries of Ceylon

How the Pearl Bearing Oysters are Gathered by Naked Divers

By R I Geare

The finding of large and valuable pearls has been a matter of deep interest to mankind for centuries The Ceylonese fisheries which had been operated at intervals since long before the Christian era are probably the most ancient of these fisheries The most perfect pearl ever discovered in that region was bought in 1633 by the Shah of Persia for about $51 000 from an Arab who brought it from Catifa a fishery opposite Bhareen in the Persian Gulf Another magnificent pearl—a black specimen—was sold to a New York firm not many years ago for about $25 000

The true pearl oyster known scientifically as *Meleagrina margaritifera* and belonging to the family Aviculidae differs from the edible oyster in having a small 'foot and anterior adductor muscle a well-developed byssus gland which secretes a bunch of fibers by which the animal is attached to rock or stone and a thick 'mother of pearl layer to the shell

The Ceylon fisheries are operated on banks covering an extensive area off the north coast of the island Tradition has it that King Solomon obtained some of his wonderful pearls from the Ceylon banks and even the pearls which Cleopatra dissolved and drank are credited with a Ceylonese origin

The banks most famous in past times lie close to the shore in the Gulf of Mannar near a place called Marichchukkaddi

At one time when Ceylon was under the Tamil power the pearl fisheries were conducted frequently and successfully They were watched over by a Tamil princess who was carried to the end of the Karaittiva Point, and there enthroned until the fishery was over to prevent robbery on the part of the divers

One of the earliest mentions of pearl fisheries in Ceylon occurs in the Rajavali chronicle (306 B C) where they are spoken of as being located near Colombo but they were unfortunately destroyed by an inundation from the sea

During the Portuguese control of the island of Ceylon there is no record of any pearl fishing but during the 140 years it was occupied by the Dutch there were at least four important fisheries between 1732 and 1749 in the course of which probably not less than a million dollars worth of pearls were secured

During the British occupancy of Ceylon which still exists the pearl banks have been under the inspectorship of the Master Attendant of the port of Colombo while the government agent of the Northern Province acts as Official Superintendent

The oyster beds are formed by an amalgam of coarse granite sand and old oyster shells cemented together with coral lime Here there is but little movement of the sand so that the oysters remain easily accessible but away from the beds the sand which is loose is formed into huge waves which have the effect of covering up and destroying the oysters immediately

The life of a Ceylon pearl oyster is not more than eight years and from about its third year it seems to be most productive both in the number and size of pearls As a matter of fact very few 8 year oysters contain valuable pearls but when a bed of oysters is fished just as they are dying off with old age the pearls obtained are liable to be many and large

True pearls which are in fact, the result of a disease sometimes brought about by the introduction into the shell of some foreign body such as a grain of sand an undeveloped egg a parasite, etc are formed in the tissue of the oyster and when they reach such a size as to cause great discomfort to the oyster the latter either dies or forces the pearl toward the opening between the valves where it is retained by an absolutely transparent substance or skin and here it increases in growth.

Owing to the monsoons pearl fishing can be carried on only in March and April During the preceding fall or early winter (generally in November) the inspector causes some 20 000 oysters to be lifted and if the average is satisfactory the fishery is ordered When the proper time arrives the boats each containing divers who work five at a time are rowed or sailed to the banks Each pair of divers has an attendant known as a manduck The boat also contains a tindal or representative of the owner of the boat and a peon who represents the interests of the government.

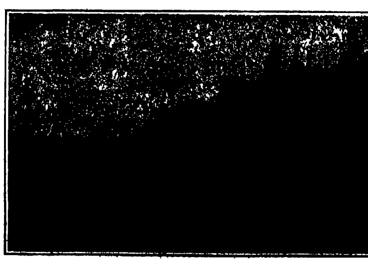
The divers are allowed for payment one third of the oysters taken while the government auctions off the remainder on the beach the same evening they are caught. The oysters are then placed by the purchasers in kottus or inclosures and are allowed to rot for eight or ten days in some receptacle—often a wooden canoe—which is covered over to shade the oysters from the sun but permits flies to obtain free access as they assist in the process of rotting Later the whole mass is washed with clean water the shells stones and byssus (or green string like substance by which the oyster attaches itself to the rock) are picked out and the residue placed on long strips of black calico to dry During the drying process the whole mass is picked over and over again and carefully scrutinised for the smallest pearls

In classifying the pearls a series of brass cullenders or baskets is used They are about the size of an ash tray and are provided with holes which are of even size in each basket. The one with the largest sized holes has twenty of them while others have as many as several hundred holes each By this method of sifting the larger pearls are readily preserved but the tiny seed pearls are often accidentally left in large numbers near the oyster washing place and for a long time afterward men and women search the sands for these minute treasures

Seed pearls it may be explained are chiefly used by Indian princes being pounded into powder to form chunam for betel-chewing and they are also extensively employed in embroideries and cluster necklaces.

The actual operation of diving for pearl oysters is in this wise When the divers are ready they climb over the side of the vessel place one foot on a large stone which is held clear of the boat by two poles fastened

Pearl oysters in a Kottu, or rotting inclosure



Pearl fishers landing their catch

at right angles over the boat's side, and by a third pole which lies parallel to the length of the vessel and is lashed to each end of the other two.

Grasping the rope which is attached to this stone and hitching over his arm the rope attached to the basket in which the diver places his catch, he takes a deep breath, closing his nostrils with his free hand, and slightly raising himself—to add impetus to his descent —gives the signal to the "manduck" to release the rope to which the stone is fastened. On reaching the bottom the diver lets go of the stone, which is then hauled up, so as to be ready for the next descent, and, swimming on the bottom, grasps all the oysters within his reach. When his breath is nearly exhausted, the diver signals to be pulled up with his basket and rises partly by his own initiative. Occasionally the divers are severely stung by jellyfishes, and sometimes they stay down too long and, actuated by avarice or overestimating their own strength, are brought up dead. When collecting the oysters they seem to float on the bottom of the sea, with backs arched and heels above their heads, while their long hair waves in a graceful manner and is upheld by the action of the water. A Tamil diver remains below from 50 to 60 seconds, but an Arab can stay down from 80 to 90 seconds.

Diving bells were imported into Ceylon by Sir Edwards Barnes in 1825, but they nor Europeans in a diving dress can compete with the naked diver.

The catch of one boat for a successful week's fishing should total about 180,000 oysters.

X-Rays and Crystalline Structure*

Discoveries That Assist in the Understanding of Theories of X-Rays and Light

By Prof. William H. Bragg

Two years have gone by since Dr. Laue made his surprising discovery of the interference effects accompanying the passage of X-rays through crystals. The pioneer experiment has opened the way for many others, and a very large amount of work, theoretical and practical, has now been done. As the preliminary exploration of the new country has proceeded, our first estimate of its resources has grown continuously; we have learned many things which help us to a better understanding of phenomena already familiar, and we have seen avenues of inquiry open out before us which as yet there has been little time to follow. The work is full of opportunities for exact quantitative measurements, where precision is sure to bring its due reward. There is enough work in sight to absorb the energies of many experimenters, and there is sure to be far more than we can see. When we consider the wideness of the new field, the quality and quantity of the work to be done in it, and the importance of the issues, we are scarcely guilty of over-statement if we say that Laue's experiment has led to the development of a new science.

The experiment itself, to put it very briefly, constitutes a proof that X-rays consist of extremely short ether waves. In order to appreciate the value of this demonstration, we must bear in mind the present conditions of our knowledge of the laws of radiation in general. Let us consider very shortly how the whole matter stood when the new work was begun.

When X-rays were first discovered eighteen years ago it was soon pointed out that they might consist of electro-magnetic disturbance of the ether analogous to those supposed to constitute light. It was true that the new rays seemed to be incapable of reflection, refraction, diffraction and interference, which were familiar optical phenomena. But it was pointed out by Schuster[1] that these defects could be explained as natural consequences of an extremely small wave-length. The positive evidence consisted mainly in the knowledge that the impact of the electrons on the anti-cathode of the X-ray bulb ought to be the occasion of electro-magnetic waves of some sort, and in the discovery by Barkla that the X-rays could be polarised, which last is a property also of light.

As experimental evidence accumulated, a number of results were found which the electro-magnetic theory was unable to explain, at least in a direct and simple manner. They were mainly concerned with the transference of energy from place to place. In some way or other the swiftly moving electron of the X-ray bulb transfers its energy to the X-ray, and the X-ray in its turn communicates approximately the same quantity of energy to the electron which originates from matter lying in the track of the X-ray, and which is apparently the direct cause of all X-ray effects. Experiment seemed to indicate that X-ray energy traveled as a stream of separate entities or quanta, the energy of the quantum differing according to the quality of the X-ray. It looked at one time as if it might be the simplest plan to deny the identity in nature of X-rays and light, to describe the former as a corpuscular radiation and the latter as a wave motion. Otherwise, it seemed that the electro-magnetic hypothesis would be torn to pieces in the effort to hold all the facts together.

But it appeared on a close examination of light phenomena also, though in much less obvious fashion, that the very same effects occurred which in the case of X-rays were so difficult to explain from an orthodox point of view. In the end it became less difficult to deny the completeness of the orthodox theory than the identity in nature of light and X-rays. Modern work on the distribution of energy in the spectrum, and the dependence of specific heat upon temperature, has also led independently to the same point of view. It has been urged with great force by Planck, Einstein, and others that radiated energy is actually transferred in definite units or quanta, and not continuously; as if we had to conceive of atoms of energy as well as of atoms of matter. Let it be admitted at once that the quantum theory and the orthodox theory appear to stand in irreconcilable opposition. Each by itself correlates great series of facts; but they do not correlate the same series. In some way or other the greater theory must be found, of which each is a partial expression.

The new discovery does not solve our difficulty at once, but it does two very important things. In the first place, it shows that the X-rays and light are identical in nature; in fact, it removes every difference except in respect to wave-length. The question as to the exact place where the difficulty lies is decided for us, we are set the task of discovering how a continuous wave motion, in a continuous medium, can be reconciled with discontinuous transferences of radiation energy. Some solution there must be to this problem. The second important thing is that the new methods will surely help us on the way to find that solution. We can now examine the X-rays as critically as we have been able to study light, by means of the spectrometer. The wave-length of the X-ray has emerged as a measurable quantity. The complete range of electro-magnetic radiations now lies before us. At one end are the long waves of wireless telegraphy, in the middle are first the waves of the infra-red detected by their heating effects, then the light waves, and then the short waves of the ultra-violet. At the other end are the extremely short waves that belong to X-radiation. In the comparative study of the properties of radiation over this very wide range we must surely find the answer to the greatest question of modern physics.

So much for the general question. Let us now consider the procedure of the new investigations, and afterwards one or two applications to special lines of inquiry.

The experiment due to Laue and his collaborators Friedrich and Knipping has already been described in this lecture room and is now well known. A fine pencil of X-rays passes through a thin crystal slip and impresses itself on a photographic plate. Round the central spot are found a large number of other spots, arranged in a symmetrical fashion, their arrangement clearly depending on the crystal structure. Laue had anticipated some such effect as the result of diffraction by the atoms of the crystal. His mathematical analysis is too complicated to be described now, and indeed it is not in any circumstances easy to handle. It will be better to pass on at once to a very simple method of apprehending the effect which was put forward soon after the publication of Laue's first results. I must run the risk of seeming to be partial if I point out the importance of this advance, which was made by my son W. Lawrence Bragg. All the recent investigations of X-ray spectra and the examination of crystal structure and of molecular motions which have been carried out since then have been rendered possible by the easy grasp of the subject which resulted from the simpler conception.

Let us imagine that a succession of waves constituting X-radiation falls upon a plane containing atoms, and that each atom is the cause of a secondary wavelet. In a well known manner, the secondary wavelets link themselves together and form a reflected wave. Just so a sound wave may be reflected by a row of palings, and very short sound waves by the fibers of a sheet of muslin.

Suppose a second plane of atoms to lie behind the first and to be parallel to it. The primary wave, weakened somewhat by passing through the first plane, is again partially reflected by the second. When the two reflected pencils join it will be of great importance whether they fit crest to crest and hollow to hollow, or whether they tend to destroy each other's effect. If more reflecting planes are supposed, the importance of a good fit becomes greater and greater. If the number is very large, then, as happens in many parallel cases in optics, the reflected waves practically annul each other unless the fit is perfect.

It is easily seen that the question of fit depends on how much distance a wave reflected at one plane loses in comparison with the wave which was reflected at the preceding plane: the fit will be perfect if the loss amounts to one, two, three, or more wave-lengths exactly. In its turn the distance lost depends on the spacing of the planes, that is to say, the distance from plane to plane, on the wave-length, and on the angle at which the rays meet the set of planes.

The question is formally not a new one. Many years ago Lord Rayleigh discussed it in this room, illustrating his point by aid of a set of muslin sheets stretched on parallel frames. The short sound waves of a high pitched bird call were reflected from the set of frames and affected a sensitive flame; and he showed how the spacing of the planes must be carefully adjusted to the proper value in relation to the length of wave and the angle of incidence. Rayleigh used the illustration to explain the beautiful color of chlorate of potash crystals. He ascribed them to the reflection of light by a series of parallel and regularly spaced twinning planes within the crystal, the distance between successive planes bearing, roughly, the same proportion to the length of the reflected wave of light at the distance between the muslin sheets to the length of the wave of sound.

Our present phenomenon is exactly the same thing on a minute scale; thousands of times smaller than in the case of light; and many millions of times smaller than in the case of sound.

By the kindness of Prof. R. W. Wood I am able to show you some fine examples of the chlorate of potash crystals. If white light is allowed to fall upon one of them, the whole of it is not reflected. Only that part is reflected which has a definite wave-length or something very near to it, and the reflected ray is therefore highly colored. The wave length is defined by the relation already referred to. If the angle of incidence is altered, the wave length which can be reflected is altered, and so the color changes.

It is not difficult to see the analogy between these cases and the reflection of X-rays by a crystal. Suppose, for example, that a pencil of homogeneous X-rays meets the cube face of such a crystal as rocksalt. The atoms of the crystal can be taken to be arranged in planes parallel to that face, and regularly spaced. If the rays meet the face at the proper angle, and only at the proper angle, there is a reflected pencil. It is to be remembered that the reflection is caused by the joint action of a series of planes, which, in this case, are parallel to the face, it is not a reflection by the face itself. The face need not even be cut truly; it may be unpolished or deliberately roughened. The reflection takes place in the body of the crystal, and the condition of the surface is of little account.

The allotment of the atoms to a series of planes parallel to the surface is not, of course, the only one possible. For example, in the case of a cubic crystal, parallel planes containing all the atoms of the crystal may also be drawn perpendicular to a face diagonal of the cube, or to a cube diagonal, or in many other ways. We may cut the crystal so as to show a face parallel to any series, and then place the crystal so that reflection occurs, but the angle of incidence will be different in each case since the spacings are different. It is not necessary to cut the crystal except for convenience. If wave-length, spacing, and angle between ray and plane are rightly adjusted to each other, reflection will take place in the crystal independently of any surface arrangement.

This is the "reflection" method of explaining the Laue photograph. W. L. Bragg showed in the first place that it was legitimate, and in the second, that it was able to explain in the position of all the spots which Laue found upon his photographs. The different spots are

* Read before the Royal Institution of Great Britain, June 5th, 1914.

[1] Nature, January 23rd, 1896.

reflections in different series of planes which may be drawn to contain the atoms of the crystal. The simpler conception led at once to a simpler procedure. It led to the construction of the X ray spectrometer which resembles an ordinary spectrometer in general form except that the grating of prism is replaced by a crystal and the telescope by an ionisation chamber and an electroscope. In use a fine pencil of X rays is directed upon the crystal, which is steadily turned until a reflection leaps out and the angle of reflection is then measured. *If we use different crystals or different faces of* the same crystal but keep the rays the same we can compare the geometrical spacings of the various sets of planes. If we use the same crystals always but vary the source of X rays we can analyse the latter measuring the relative wave lengths of the various constituents of the radiation.

We have thus acquired a double power. (1) We can compare the intervals of spacing of the atoms of a crystal or of different crystals along various directions within the crystal: in this way we can arrive at the structure of the crystal. (2) We can analyse the radiation of an X ray bulb: in fact we are in the same position as we should have been in respect to light if our only means of analysing light had been the use of colored glasses and we had then been presented with a spectrometer or some other means of measuring wave-length exactly.

We now come to a critical point. If we knew the exact spacings of the planes of some one crystal we could now by comparison find the spacing of all other crystals and measure the wave-length of all X radiations: or if we knew the exact value of some one wave length we could find by comparison the values of all other wave-lengths and determine the spacings of all crystals. But as yet we have no absolute value either of wave length or of spacings.

The difficulty appears to have been overcome by W. L. Bragg's comparison of the reflecting effect in the case of rocksalt or sodium chloride and sylvine or potassium chloride. These two crystals are known to be isomorphous: they must possess similar arrangements of atoms. Yet they display a striking difference both in the Laue photograph and on the spectrometer. The reflections from the various series of planes of the latter crystal show spacings consonant with an arrangement in the simplest cubical array of which the smallest element is a cube at each corner of which is placed the same group, a single atom or molecule or group of atoms or molecules. In the case of rocksalt the indications are that the crystal possesses a structure intermediate between the very simple arrangement just described and one in which the smallest element is a cube having a similar group of atoms or molecules at every corner and at the middle point of each face. The arrangement is called by crystallographers the face centered cube. The substitution of the sodium for the potassium atom must transform one arrangement into the other. This can be done in the following way if we accept various indications that atoms of equal weight are to be treated as equivalent. Imagine an elementary cube of the crystal pattern to have an atom of chlorine at every corner and in the middle of each face and an atom of sodium or potassium as the case may be at the middle point of each edge and at the center of the cube. We have now an arrangement which fits the facts exactly. The weights of the potassium and chlorine atoms are so nearly the same as to be practically equivalent and when they are considered to be so the arrangement becomes the simple cube of sylvine. But when the lighter sodium replaces the potassium as in rocksalt the arrangement is on its way to be that of the face centered cube and would actually become so were the weight of the sodium atoms negligible in comparison with those of chlorine. Of course the same result would follow were two or three or any number of atoms of each sort to take the place of the single atom provided the same increase were made in the number of atoms of both sorts. We might even imagine two sorts of groups of chlorine and metal atoms, one containing a preponderance of the former the other of the latter but so that two groups one of each kind contain between them the same proportion of chlorine and metal as the crystal does. We must merely have two groups which differ in weight in the case of rocksalt and are approximately equal in the case of sylvine. But it was best to take the simplest supposition at the outset and now the evidence that the right arrangement has been chosen is growing as fresh crystals are measured. For it turns out that in all crystals so far investigated the number of atoms at each point must always be the same. Why then should it be more than one? Or in other words if atoms are always found in groups of a certain number ought not that group to be called the atom?

As soon as the structure of a crystal has been found we can at once find by simple arithmetic the scale on which it is built. For we know from other sources the weight of individual atoms, and we know the total weight of the atoms in a cubic centimeter of the crystal. In this way we find that the nearest distance between two atoms in rocksalt is 2.81×10^{-8} centimeters which distance is also the spacing of the planes parallel to a cube face. From a knowledge of this quantity the length of any X ray wave can be calculated at once as soon as the angle of its reflection by the cube face has been measured. In other words the spectrometer has now become a means of measuring the length of waves of any X radiation and the actual spacings of the atoms of any crystal.

From this point the work branches out in several directions. It will not be possible to give more than one or two illustrations of the progress along each branch.

Let us first take up the most interesting and important question of the characteristic X rays. It is known that every substance when bombarded by electrons of sufficiently high velocity emits X rays of a quality characteristic of the substance. The interest of this comparison lies in the fact that it displays the most fundamental properties of the atom. The rays which each atom emits are characteristic of its very innermost structure. The physical conditions of the atoms of a substance and their chemical associations are largely matters of the exterior but the X rays come from the interior of the atoms and give us information of an intimate kind. What we find is marked by all the simplicity we should expect to be associated with something so fundamental.

All the substances of atomic weight between about 30 and 130 give two strongly defined lines: that is to say there are found among the general heterogeneous radiation two intense almost homogeneous sets of waves. For instance rhodium gives two pencils of wave lengths approximately equal to 0.61×10^{-8} centimeters and 0.54×10^{-8} centimeters respectively. More exactly the former of these is a close doublet having wave-lengths 0.619×10^{-8} and 0.614×10^{-8}. The wave lengths of palladium are nearly 0.58×10^{-8} and 0.51×10^{-8}; nickel 1.66×10^{-8} and 1.50×10^{-8}. Lately Moseley has made a comparative study of the spectra of the great majority of the known elements and has shown that the two line spectrum is characteristic of all the substances whose atomic weights range from that of aluminium 27 to that of silver 108. These X rays constitute there is no doubt whatever the characteristic rays which Barkla long ago showed to be emitted by this series of substances.

Now comes a very interesting point. When Moseley sets the increasing atomic weights against the corresponding decreasing wave lengths the changes do not run exactly parallel with each other. But if the wave lengths are compared with a series of natural numbers everything runs smoothly. In fact it is obvious that the steady decrease in the wave length as we pass from atom to atom of the series in the periodic table implies that some fundamental element of atomic structure is altering by equal steps. There is excellent reason to believe that the change consists in successive additions of the unit electric charge to the nucleus of the atom. We are led to think of the magnitude of the nucleus of any element as being simply proportional to the number indicating the place of the element in the periodic table: hydrogen having a nuclear change of one unit, helium two and so on. The atomic weights of the successive elements do not increase in an orderly way: they mount by steps of about two but not very regularly and sometimes they seem absolutely to get into the wrong order. For example nickel has an atomic weight of 58.7 whereas certain chemical properties and still more its behavior in experiments on radio activity indicate that it should lie between cobalt (59) and copper (63.6). But the wave lengths, which are now our means of comparison, diminish with absolute steadiness in the order cobalt nickel copper. Plainly the atomic number is a more fundamental index of quality than the atomic weight.

It is very interesting to find in the series arranged in this way four and only four gaps which remain to be filled by elements yet undiscovered.

Let us now glance at another and most important side of the recent work, the determination of crystalline structure. We have already referred to the case of the rocksalt series but we may look at it a little more closely in order to show the procedure of crystal analysis.

The reflection of a pencil of homogeneous rays by a set of crystalline planes occurs as already said at a series of angles regularly increasing, giving as we say spectra of the first, second, third orders and so on. When the planes are all exactly alike and equally spaced the intensities of the spectra decrease rapidly as we proceed to higher orders, according to a law not yet fully explained. This is, for example, the case with the three most important sets of planes of sylvine, those perpendicular to the cube edge, the face diagonal and the cube diagonal respectively. An examination of the arrangement of the atoms in the simple cubical array of sylvine shows that for all these sets the planes are evenly spaced and similar to each other. It is to be remembered that the potassium atom and the chlorine atom are so nearly equal in weight that they may be considered effectively equal. In the case of rocksalt the same may be said of the first two sets of planes, but not of the third. The planes perpendicular to the cube diagonal are all equally spaced but they are not all of equal effect. They contain alternately chlorine atoms (atomic weight 35.5) only and sodium atoms (atomic weight 23) only. *The effect of this irregularity on the* intensities of the spectra of different orders is to enhance the second, fourth and so on in comparison with the first, third, and fifth. The analogous effect in the case of the light is given by a grating in which the lines are alternately light and heavy. A grating specially ruled for us at the National Physical Laboratory shows this effect very well. This difference between rocksalt and sylvine and its explanation in this way constituted an important link in W. Lawrence Bragg's argument as to their structure.

When therefore we are observing the reflections in the different faces of a crystal in order to obtain data for the determination of its structure we have more than the values of the angles of reflection to help us: we have also variations of the relative intensities of the spectra. In the case just described we have an example of the effect produced by want of similarity between the planes, which are however uniformly spaced.

In the diamond on the other hand we have an example of an effect due to a peculiar arrangement of planes which are otherwise similar. The diamond crystallises in the form of a tetrahedron. When any of the four faces of such a figure is used to reflect X rays it is found that the second order spectrum is missing. The analogous optical effect can be obtained by ruling a grating so that as compared with a regular grating of the usual kind the first and second, fifth and sixth, ninth and tenth alone are drawn. To put it another way two are drawn, two left out, two drawn, two left out and so on. The National Physical Laboratory has ruled a special grating of this kind also for us and the effect is obvious. The corresponding inference in the case of the diamond is that the planes parallel to any tetrahedral face are spaced in the same way as the lines of the grating. Every plane is three times as far from its neighbor on one side as from its neighbor on the other. There is only one way to arrange the carbon atoms of the crystal so that this may be true. Every atom is at the center of a regular tetrahedron composed of its four nearest neighbors, an arrangement best realized by the aid of a model. It is a beautifully simple and uniform arrangement and it is no matter of surprise that the symmetry of the diamond is of so high an order. Perhaps we may see also in the perfect symmetry and consequent effectiveness of the forces which bind each atom to its place an explanation of the hardness of the crystal.

Here then we have an example of the way in which peculiarities of spacing can be detected. There are other crystals in which want of uniformity both in the spacings and in the effective value of the planes combine to give cases still more complicated. Of these are iron pyrites, calcite, quartz and many others. It would take too long to explain in detail the method by which the structures of a large number of crystals have already been determined. Yet the work done already is only a fragment of the whole and it will take no doubt many years even though our methods improve as we go on before the structures of the most complicated crystals are satisfactorily determined.

On this side then we see the beginning of a new crystallography which though it draws freely on the knowledge of the old yet builds on a firmer foundation since it concerns itself with the actual arrangement of the atoms rather than the outward form of the crystal itself. We can compare with the internal arrangements we have now discovered the external forms which crystals assume in growth and the modes in which they tend to come apart under the action of solvents and other agents. By showing how atoms arrange and disarrange themselves under innumerable variations of circumstances we must gain knowledge of the nature and play of the forces that bind the atoms together.

There is yet a third direction in which inquiry may be made though as yet we are only at the beginning of it. In the section just considered we have thought of the atoms as at rest. But they are actually in motion and the position of an atom to which we have referred so frequently must be an average position about which it is in constant movement. Since the atoms are never exactly in their places, the precision of the joint action on which the reflection effect depends suffers materially. The effect is greater the higher the order of the spectrum. When the crystal under examination is contained within a suitable electric furnace and the atoms vibrate more violently through the rise of temperature,

the intensities of all orders diminish, but those of higher order much more than those of lower. The effect was foreseen by the Dutch physicist Debije and the amount of it was actually calculated by him on certain assumptions. I have found experimental results in general accord with this formula. In passing it may be mentioned that as the crystal expands with rise of temperature the spacing between the planes increases and the angles of reflection diminish, an effect readily observed in practice.

This part of the work gives information respecting the movements of the atoms from their places, the preceding respecting their average positions. It is sure, like the other, to be of much assistance in the inquiry as to atomic and molecular forces and as to the degree to which thermal energy is locked up in the atomic motions.

This brief sketch of the progress of the new science in certain directions is all that is possible in the short time of a single lecture, but it may serve to give some idea of its fascination and possibilities.

The Geology of the Yellowstone National Park

A Striking Topographical Structure and a Complete Geological Problem

By Carl Hawes Butman

In the year 1872 Congress set aside a tract of land in the the northwest corner of Wyoming for the benefit of mankind and the preservation of the natural wonders of the country. This became known as the Yellowstone National Park and was the first tract thus set aside for this purpose. It includes some 3 340 square miles but in relation to the whole of Wyoming it appears on the map as a misplaced postage stamp which like many stamps overlaps the letter by extending a little way into both Montana and Idaho. Following the precedent thus established 40 years ago Congress has since established eleven smaller parks in various places where the public might find recreation and where the wonders of nature therein might be preserved from desecration.

From the point of view of the geologist Yellowstone Park is in a way unique. Its central plateau with the adjacent mountains presents a sharply defined region contrasting with the remainder of the northern Rocky Mountains a striking piece of topographical structure and a complete geological problem. The central portion consists of a broad elevated irregular plateau of volcanic origin some 40 miles square, extending between 7 000 and 8 500 feet above sea level and surrounded on the north, northwest, south, east and northeast by mountain ranges, the peaks and highest points of which extend upward like a gigantic wall for 2 000 to 4 000 feet more.

Just south of the park the Tetons, the highest and grandest peaks in the northern Rocky Mountains, stand out prominently, but only the outlying spurs come within the limits of the park proper. These mountains are composed mostly of coarse crystalline gneisses and shists probably of Archean age abutted on the northern spurs by upturned Paleozoic strata.

On the eastern edge of the park the Absaroka Range stretches from the north to the south where it connects with the northern end of the Wind River Range. For more than 80 miles this range presents a bold unbroken barrier along the eastern side of the park, its highest peaks towering 10 000 or 11 000 feet aloft.

At the northeastern corner of the park an irregular mass of mountains joins the Absarokas with the Snowy Range which forms the northern boundary of the reservation with its rough snow-covered elevations. The rocks of the southern slopes of the Snowy Range which extend into the park are composed mainly of granite gneiss and shist, while their sedimentary beds belong to the pre-Cambrian series.

Enclosing the park on the northwestern corner lies the Gallatin Range, separated from the Snowy Range on the east by the valley of the Yellowstone River. It is a beautiful mountain range presenting diversified forms as well as varied geological problems. Its crowning glory, Electric Peak, 11 100 feet in height and incidentally the tallest peak in this region, gets its name from the magnetic disturbances discovered by the first explorers to carry surveying instruments up its slopes. An important part of the Gallatin Range is formed of Archean gneisses covered with a series of limestone, sandstone and shale beds, both of the Paleozoic and Mesozoic eras, representing Cambrian, Silurian, Devonian, Carboniferous, Triassic, Jurassic and Cretaceous periods. Large masses of intrusive rocks closely allied with the sedimentary beds have taken an important part in creating the present structural features of this range. They are of the andesitic type and cover a broad range of mineral composition including pyroxene, hornblende and hornblende-mica.

The general region of the park was at one time subjected to severe dynamic action which affected all the ranges at about the same time, and probably occurred during the latter part of the Cretaceous period although the work of mountain building seems to have continued into the Middle Tertiary period. During the latter period the site of the park was torn up by volcanic action which continued to a lesser extent through the Pliocene and into the Quaternary periods. All such action has long since ceased, but the volcanic rocks remain offering much interesting information. They comprise three groups which succeeded each other, andesites with basalts, rhyolites, and basalts. Probably the andesitic eruptions continued for the greatest period of time since there are evidences of plant life buried under 2 000 feet of volcanic material.

In Tertiary times there is supposed to have existed a large volcano named the Sherman, and of which Mount Washburn is a more recent crater, the bursting forth of which caused the destruction of the original crater of the older volcano. Recent eruptions and erosions have so destroyed the early volcanic flows that it is difficult to identify the ancient andesitic lava which was afterwards submerged by immense quantities of rhyolite to a thickness of nearly 8 500 feet. In fact nothing else remains to be seen but rhyolitic rock, except the mineral spring deposits and the remains of the early crater rim on Mount Washburn. Another source of the rhyolite flows is supposed to have been Mount Sheridan in the southern part of the reservation, which towers to a height of 10 385 feet and offers a remarkable view of the volcanic region stretching across the park from east to west. The deep gorges of the Yellowstone, Gibbon and Madison Rivers have not worn through this tremendous thickness of rock and only in the Grand Canyon of the Yellowstone are the ancient andesitic breccias exposed beneath the rhyolites, while nowhere are the sedimentary beds revealed. The central plateau includes the finest examples of structural forms, crystallization and mode of origin of acidic lavas, varying from a nearly holocrystalline rock to pure volcanic glass, that can be found in the world.

Following the rhyolite eruption there came a period of faulting and displacement, succeeded by eruptions of basalt which however deposited but a thin layer over the rhyolite and did practically nothing to change the physical aspect of the country. The glacial action which soon occurred nevertheless carved out the early drainage channels, cut gorges into the rhyolite lava and shaped the two volcanoes into their present form. Traces of the ancient glaciers are to be found nearly everywhere, especially in the several mountain ranges, while in the Tetons there exist to-day glaciers characteristic of the ancient grand system which extended over the entire plateau. Erosion continued the work of the glaciers in remodeling the park surface, and this action has carved since that time the deep gorges of the Madison, Gibbon and Yellowstone rivers, veritable canyons cut to a depth of nearly 1 500 feet and several miles in length.

Much evidence of the great glacial action is still at hand, the valley of the lower Yellowstone River is strewn with rocks brought by the glacier from both the east and west borders of the park. One example of the tremendous force of the ice floes of the early times is a great granite bowlder (about 20 feet in diameter) brought down and deposited on the brink of the Grand Canyon. It is completely isolated from its fellows and quite 30 miles from where it must have been transported. The glacial action took place since the travertine deposits of the hot springs were formed. This is shown especially at Terrace Mountain near the Mammoth Hot Springs, where the travertine covering the rhyolite plateau is strewn with glacial bowlders brought from the Gallatin Range some 15 miles away, indicating that the travertine is older than the glacier.

Probably the most interesting feature of the park to-day is the series of hot-water fountains or geysers which occur in three principle localities, Norris, Lower and Upper Basins, and include 16, 23 and 45 geysers respectively. The first group is located on the Gibbon Canyon Road about 20 miles south of the Mammoth Hot Springs. The second, about 20 miles farther to the south near the Fountain Hotel, is 7 240 feet in altitude and largest of the three basins, but its individual geysers are scattered over a considerable area and not as available for inspection. The Upper Basin offers the most interesting and largest fountains. The Giant Geyser, which plays every seven or twelve days for about an hour, is the largest of the park geysers since the Excelsior of the Lower Basin ceased to play in 1888. It shoots a stream of hot-water and steam to a height of between 200 and 250 feet. Another famous geyser of this basin is Old Faithful, situated in the southernmost part at an altitude of 7,300 feet. This geyser has the reputation of maintaining a regular schedule as it plays every 60 or 75 minutes for a period of about 4 minutes, shooting its water column aloft for 125 or more feet, and has kept to its schedule since its discovery in 1870. One geologist has estimated its flow at 3 000 barrels per eruption.

Although the park's volcanoes are extinct the steam fountains which still exist are dependent upon the heated rocks and gases far below the surface which raise the temperature of the percolating surface waters under great pressure and cause them to return to the surface with tremendous energy, often bursting out in fountains of hot-water and steam. Other theories as to the origin of geysers have been advanced, that they are caused by chemical action or burning coal, but of late scientists have shown that geysers and hot-water springs are only found in regions where volcanic rock abounds, and the general conclusion points out that the steam source is the still hot lava deep within the earth.

The ascending steam and hot-water have caused great geological changes in the surface rocks through which they have passed, as may be seen at many points in the park, especially in the Grand Canyon of the Yellowstone, where the walls are colored for three miles below the Lower Falls by this action. Fully 1 000 feet of the wall from the brink to the water below is decomposed rhyolite varying in hue through orange, red, purple and yellow. Here too the ancient steam vents may be descried, while at the bottom of the canyon there are steam vents, hot springs and fumaroles which are still active.

Besides enabling the scientist to study the old vents and the discoloration of the walls, the Grand Canyon offers a fine example of erosion conducted on an immense scale within recent geological times, and its course was obviously determined by the easily eroded decomposed rocks caused by the ascending steam and hot-water mentioned above. The two falls of the Yellowstone offer another feature of interest to the student since they present a graphic example of the wearing effect of water upon the rocky walls and bed. The Lower Falls are the larger, being 308 feet in sheer drop.

The Mammoth Hot Springs are located 4 miles south of the northern park entrance at Gardiner and here also is situated the hotel of that name together with the army post. Southwest of the hotel is Terrace Mountain, an outlying ridge of the rhyolite plateau which is covered with thick beds of travertine deposited by the hot water in the form of terraces from which the mountain derives its name. The deposits of the hot springs at this place are far different from those upon the plateau. Here they are nearly pure travertine with traces of silica, analyses indicate about 97 per cent calcium carbonate, while on the plateau the greater part of the deposits are of siliceous sinter called geyserite. This variation is on account of the fact that the Mammoth Springs are formed by steam coming up from far below through the water of the Mesozoic strata, the Cretaceous limestones furnishing the lime held in solution and deposited on the surface as travertine, while the mineral constituents of the plateau waters are derived mainly from highly acidic lavas carrying only a small portion of lime.

The terraces of the Mammoth Hot Springs present the appearance of banks of ice and snow with irregular basins of water in their glimmering stepped terraces. Among the important ones are Minerva, Cleopatra, Hymen, Pulpit, Jupiter and Mound Terraces, while the springs which flow into and over them are named Jupiter, Diana, Palette, Naiad and others. The coloring of the spring waters here is marvelous in its harmony and brilliant tints, and is due to Algae which grow in hot water up to a temperature of about 185 deg. Fahr. Many of the springs present the appearance of boiling caldrons of water although this is not the case, the bubbles being formed by escaping carbonic-acid gas.

Yellowstone Park, with its many geological formations, its ancient volcanoes, lava flows, hot springs and geysers, presents a wonderful natural laboratory for the geologist as well as the chemist. Its formation dates back to that of the central table land of the continent, and yet changes are still going on within its limits, though not as actively as heretofore, which make it an ever interesting problem for the scientist.

Purification of Water by the Ultra-Violet Rays*

Principles Underlying the Most Recent System for Destroying Germ Life

By M. von Recklinghausen, Ph.D.

It is a matter of common knowledge nowadays that the ultra violet rays have a strong bactericidal power. Within the last few years this power of annihilating microbes by ultra violet rays has been applied for freeing water of germs and a new industry has sprung up which produces water purifiers that make use of this new principle to sterilize water for drinking and other purposes. As this system is being applied successfully to large water plants, it is of interest for the professional water engineer to be fully informed on the principles underlying this most recent system of water purification.

The treatment of water by artificial light sources for the purpose of destroying its germ life dates back to Downs and Blunt (1878). They found that the shorter the wave lengths of the light the better the bactericidal action, and they were corroborated in this later on by Duclaux, Arloing, Roux, Geissler and others. We owe to Duclaux the theory that sunlight is the most common and cheapest disinfectant known.

Marshall Ward (189.) completed these important studies by analyzing the effect of arc spectra thrown on infected agar plates; whatever they were struck by violet and particularly by ultra violet rays they were disinfected and did not develop colonies. This English scientist sterilized Thames water by placing it in a tank equipped with a quartz window and submitting it to the rays of an arc lamp. This was proposed again later on by Lambert.

The first complete analysis of this bactericidal phenomenon of strong light sources we owe to Finsen, who in his famous light healing establishment laid the foundation of our modern knowledge of the action of light

Fig. 2.—Spectrum of quartz lamp and of sunlight

on germ life. As you will remember, the practical result of this work was the introduction of the light treatment of certain diseases by the Finsen lamp. We had however to await the arrival of really powerful sources of ultra violet rays before applying light practically as a bactericidal agent for the purification of water.

This new source of ultra violet rays was the mercury arc lamp built out of quartz. This mercury arc owes its origin to the work of Mr. Peter Cooper Hewitt, resulting in the well known Cooper Hewitt illuminating lamps. When the ordinary glass of these lamps is replaced by quartz glass, that is to say fused rock crystal, we obtain a container which allows the greatest amount of the ultra violet rays produced by the mercury arc to be sent out from the lamp.

The first to propose the application of the mercury arc for the purification of water was De Mare. His sterilizer consisted of a lamp around which the water flows in a circular path (Fig. 1). Some years later and nearly simultaneously different ways of constructing water sterilizers with mercury lamps were tried out and this work has resulted in the installation of several large and very many small ultra violet ray water purifiers.

Before going into the details of this work I will mention the principle underlying the method of water purification by ultra violet rays. We know from experiments that germs exposed directly to and at a very short distance (½ to 1 inch) from a powerful source of ultra violet rays such as we use in a modern sterilizer are killed within a small fraction of a second, in some cases one twentieth of a second being sufficient.

We therefore have to attend to two things: first, to an economic illumination of water with ultra violet rays, and second, to make sure that every microbe contained in the water will be really led through the illuminated zone.

If we consider the latter point first we come immediately to the conclusion that nothing must be in the water to intercept the rays, that is to say there must not be any suspended matter in the water in the shadow of which the germ would be protected from the rays emitted by the lamp.

SOURCE OF ULTRA VIOLET LIGHT

Practically every source of light emits some invisible ultra violet rays together with the visible rays. This can be studied by dissolving the light into its components by means of a quartz glass prism. Our human eye will see on such a spectrum only the well known colors of the rainbow. It will not see the wave-lengths below the red nor the wave lengths beyond the violet; however, the latter can be easily demonstrated by certain properties they have; for example, certain dye stuffs show a fluorescent color when struck by the ultra violet rays; also many chemical and physical reactions will take place under the influence of these ultra violet rays and prove their presence in the spectrum thereby.

The artificial sources of light which are richest in ultra violet rays are the electric arcs between metal electrodes, for instance, the iron arc, mercury arc, etc. All such arcing between metals is accompanied by disintegration of the metals themselves; therefore the electrodes have to be renewed from time to time. In the case of mercury this renewing can be done in the simplest and easiest manner, namely, by condensing the mercury escaping from the arc and leading the so condensed mercury back to the electrode contained. Of course the arc in this case has to be inclosed hermetically in a container so as to avoid loss of mercury. The material we choose for making this container must be of such a quality that the desirable rays are not held up thereby, but on the contrary are allowed to escape freely. This material for the arc container is fused

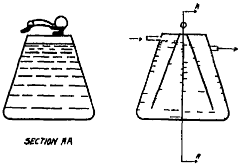
rock crystal, or more properly expressed, fused quartz.

For a given amount of electrical energy put into this arc, such a quartz arc lamp will attain a certain temperature depending upon its radiating capacity that is to say on its shape and surroundings. We have found that the amount of ultra violet rays produced by such a quartz lamp is considerably more when running at a high temperature, than when it is run at a low temperature. The production of ultra violet rays is therefore the more economical the higher the temperature of the lamp. This high temperature is obtained by raising the voltage of the lamp (Fig 4). We are however limited to a certain temperature namely about 800 deg Cent by the fact that quartz if maintained for a long time at a higher temperature will devitrify becoming thereby more or less opaque to the visible and invisible rays emitted from the arc. As in a water sterilizer we naturally want to approach the lamp as



Figs 8 and 9.—Experimental apparatus used by the writer

close as possible to the water we must be careful to consider what has just been said about temperature and prevent the water from cooling the luminous part rendering it thereby inefficient in its production of ultra violet rays.

PHYSICAL CHARACTERISTICS OF ULTRA VIOLET LIGHT

The ether vibration can be distributed in four groups according to their wave lengths namely (1) the electric rays (2) the infra red rays (3) the rays of the visible spectrum (4) the ultra violet rays.

Between the last electric rays and the first infra red rays exists probably a group of still unknown qualities. All these rays travel at the same speed namely 300 000 kilometers per second. The wave lengths are as follows:

1 Electric waves (Hertz 1888) from several kilometers down to 3 millimeters.

2 Infra red rays (Herschel 1800) from 400 down to 0.76μ [1]

3 Visible rays (Newton 1666) from 0.76μ down to 0.40μ.

4 Ultra violet rays (Ritter 1802) from 0.40μ down to 0.10μ.

We are interested to day in that last named group number 4 namely the ultra violet rays whose upper limit is more or less vague (Fig 2). It is sometimes placed at 0.3969μ, however even shorter waves can be noticed by the eye although not directly but only by the fact that the crystalline in our eyes becomes fluorescent giving thereby impression of gray on the retina. If people therefore have sometimes thought they were able to see ultra violet rays they really only saw their own crystalline. The lower limit of 0.10μ of the ultra

[1] $\mu = \frac{1}{1000}$ millimeter = 10 000 Angström units.

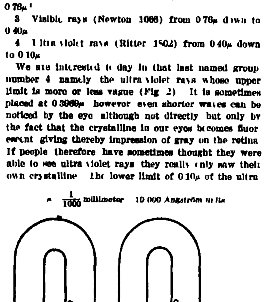


Fig. 10.—Large experimental apparatus designed to stir and circulate the water.

violet rays was obtained by Schumann and Lyman by working in vacuum with fluorspar prisms. However these very short wave lengths do not come into consideration in our case because a few millimeters of air absorb completely the wave-lengths below 0.160μ and several centimeters of air absorb the wave lengths below 0.1850μ. Several kilometers of air absorb the ultra violet from 0.2943μ down. This wave-length is therefore the shortest of the sun's waves reaching our eye and therefore the ultra violet contained in the sun's rays are only the wave-lengths between 0.40μ and 0.2943μ.

Quartz the only material which we can apply for our lamps absorbs practically everything below 0.20μ; therefore we may say that from the ultra violet ray efficiency point of view it does not matter very much whether a quartz lamp is surrounded by a thin layer of air or by vacuum. Glass absorbs ultra violet rays to an *enormous extent, as may be seen from the fact that* the bactericidal power of a quartz lamp is cut down to 1/1 000 if the lamp is surrounded by a glass tube.

BACTERICIDAL POWER OF ULTRA VIOLET RAYS

It was of interest to see whether different microbes had different resistivities against ultra violet rays in the same way that they are different against disinfectants and heat, and we come to the astonishing result that they do not vary anything like as much. For instance spores are often twenty times as resistant as the unprotected forms of germs against chemicals. We find that some are only 1.5 to 5 times as resistant against ultra violet light as ordinarily unprotected water bacteria. The table on page 10 (Fig 3) shows a comparison of different types of germs in their resistivity. In each case under similar conditions cultures were made and the free germs put in clear water care being taken however to avoid clumps of bacteria and also to avoid the presence of the nourishing medium for otherwise the germs would have been protected more or less against the rays.

It has sometimes been thought that the bactericidal action of the ultra violet rays was due to a small amount of hydrogen peroxide which indeed forms itself by the exposure of water to the ultra violet rays. However this formation is so minute that it is barely noticeable after ten hours exposure of the water and we can surely say that the bactericidal effect is not due to the action of the so formed disinfectant but is a specific typical action of the ultra violet rays on the germ. It is not likely that by the action of the rays during such a short period the entire bacteria should be chemically changed coagulated or otherwise modified but it is more probable that some ferment or similar product contained in the cell is modified by the rays and thereby poisons the system of the cell.

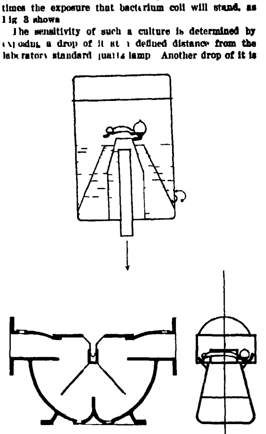
We have often been asked whether the germs struck by the light may not be simply stunned and may survive again afterwards. In answer to this I will say that the methods of making the counts in Europe would enable one to find out whether there is any reviving. These counts extended over a period of usually fifteen days and never have shown any indication of revival.

QUANTITOMETRY OF ULTRA VIOLET RAYS

The luminous power of light sources is usually measured by comparing them with standard lamps. The moment that the light one wants to measure has a color different from the standard lamp great difficulties arise based on the fact that we do not really compare the two lamps physically but only physiologically.

The difficulty of determining the *ultra violet* candle power of a lamp is far greater again as we are not sensible to these rays at all. To get some idea of the strength of ultra violet source we have therefore to *create new means and units of comparison. Many* different chemicals and physical reactions take place in the ultra violet light. One may therefore base a measure of the ultra violet candle-power on the speed and strength of such a reaction. The most typical and most convenient reaction of this kind is the blackening of photographic paper. We have found that a mercury quartz lamp will blacken paper about four times as quick as the same lamp screened behind a glass plate. An ordinary sensitometer can be built embodying this principle. Another reaction of the ultra violet rays may be considered by comparing the amount of fluorescence produced by the lamps but both of these methods of measuring will only allow us to compare light sources of similar composition. They do not give us what is really most interesting for us namely a measure of the *bactericidal power* of a lamp and we therefore thought it best to adopt a real biologic test for the measure of the abiotic strength of quartz lamps. There remains therefore nothing for us to do but to establish a standard source of ultra violet that is to say a laboratory standard composed of a certain lamp which is so kept that it is most unlikely to change in candle-power and compare the action of this lamp with the action of the lamp one wants to measure on one and the same cultures of germs. The way we proceed is as follows. We make a culture of paramecies which are very similar in their sensitivity to ultra violet rays as ordinary water bacteria. As a matter of fact they will stand about six times the exposure that bacterium coli will stand, as Fig 3 shows.

The sensitivity of such a culture is determined by exposing a drop of it at a defined distance from the laboratory standard quartz lamp. Another drop of it is



Figs 11 and 12.—Typical apparatus that stirs water being treated between successive illuminations

exposed at the same distance to the lamp one wants to measure and the time necessary for killing gives the indication of the relative value of ultra violet candle power. We have chosen paramecias because they are easily observed under a microscope having a rather violent motion while alive and naturally no motion when dead. A few observations will therefore give us within a few minutes a definite idea of the bactericidal power one wants to measure.

I may say that we have checked figures so obtained with the effect on coli cultures and can see thereby that we have a fairly safe process for determining by comparison the ultra violet candle power of a lamp.

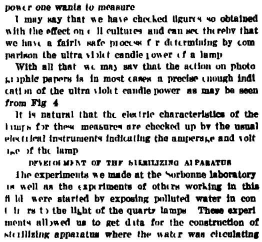
With all that we may say that the action on photographic papers is in most cases a precise enough indication of the ultra violet candle power as may be seen from Fig 4.

It is natural that the electric characteristics of the lamps for these measures are checked up by the usual electrical instruments indicating the amperage and voltage of the lamp.

DEVELOPMENT OF THE STERILIZING APPARATUS

The experiments we made at the Sorbonne laboratory as well as the experiments of others working in this field were started by exposing polluted water in contact first to the light of the quartz lamps. These experiments allowed us to get data for the construction of sterilizing apparatus where the water was circulating continually through the illuminated zone.

As examples for the simplest form of apparatus I will



Figs 13 and 14.—Showing pistol lamp applied to flumes

mention the sterilizing tank which we used in our preliminary experiments (Fig 6) and Nogier (Fig 7) and the Quarzlampen Gesellschaft (Fig 5) In all of these experiments the water was simply passed in a straight flow underneath or around the source of the ultra violet light We found the results with this type of apparatus to be irregular and came to the conclusion that this was due to the fact that the water although clear still contained some microscopic suspended matter which when the water was flowing straight would allow microbes to be shielded

We therefore considered it advantageous to expose the water a second and third time to the light after having stirred it between illuminations In this way we expected to turn over such microscopic particles and have them therefore exposed on all sides to the action of the lamps A typical case of such apparatus was used by us in experiments at the Sorbonne, and is shown in the design Figs 8 and 9 The water in a similar apparatus of considerably larger size (Fig 10) flowed through four illuminated zones and stirred itself up through its flow around the bends of the canal between the luminous zones The results were very satisfactory as we found sterilization from about 5 000 germs per cubic centimeter down to less than 10 per cubic centimeter the consumption of electric energy for the lamps being at the rate of 144 kilowatt hours per million gallons The submitting of the water to successive illuminations and stirring up during illumination can also be done with a single lamp by so arranging baffles that the water is led several times toward and away from the source of the light (Figs 8 and 9) Typical apparatus of this kind is shown in the B2 (Fig 11) and C3 (Fig 12) apparatus. The former apparatus B2 type uses only perhaps one fourth of the light emitted by the lamp However the apparatus is easy to handle and of a small size

The C3 apparatus was constructed in a somewhat different way with a view of using a greater proportion of ultra violet The lamp was protected from contact with the water by inserting it into a chamber fitted with quartz windows which chamber was submerged in the tank containing the water Three contacts of the water with the light are obtained in this apparatus

It was desired to so construct the lamps that practically all their light could enter into the water and exert its sterilizing action The so called pistol lamps which have a U shaped luminous tube (Fig 15) allow this to be realized the luminous part being inserted into quartz tubes which protect them from contact with the water (Figs 13 and 14) Such pistol lamp equipments can be inserted into flumes through which the water flows and give the water several successive illuminations (Figs 13 14) The necessary stirring action in the water is obtained by baffle plates placed in the lamp axis whereby fairly violent stirring is taking place near the lamp

The largest lamp unit made so far is the 500-volt 2 5 amperes pistol lamp and a maximum number of ten such lamps are inserted into a single flume

As to the depth of the water in sterilizing apparatus theoretically the best will be a very great depth of the water We have observed strong bactericidal action even through three feet of water the ratio being practically as may be expected inversely as the square of the distance that is to say for instance one ninth of bactericidal action at three times the distance Calculation and practice have shown us that it is good to provide if possible two feet depth of water in larger apparatus Of course in apparatus working with water which is highly colored this depth may be reduced as otherwise it would make the apparatus unnecessarily cumbersome

The whole system having been developed abroad it is only natural that there are considerably more such installations in Europe than in this country Small installations are used for producing water for drinking and surgical purposes in hospitals, schools etc also for bottling purposes The first large installation of a C3 apparatus (rate of 150 000 gallons per day) has been running since November 1910 in a suburb of Rouen The hygienic results from this plant are very satisfactory typhoid in the district fed with the water from this plant being extinct while it exists still in the surrounding districts which use similar water without ultra violet ray purification

A plant with four 220 volt pistol lamps has been running for over a year in Saint Malo sterilizing the water at a rate of 750 000 gallons per twenty four hours

Many C3 apparatus are running in France, in some cases two being run in series, with always very gratifying results The largest sterilizing unit composed of a flume with ten 500 volt pistol lamps is sterilizing the water for the city of Luneville France (Fig 16) This supply consists of 1 500 000 gallons of river water and 375 000 gallons of spring water The water in this case, which in its raw state is extremely muddy and rich in colloidal matter is filtered through a rough and slow sand filter without the addition of coagulants, at a rate of about 7 000 000 gallons per acre In case of a biological filtration this type of water would have to be filtered at the rate of 2 500 000 gallons per acre

On account of some turbidity and also an often deep color of the filtered water (up to 40 U S standard) this plant has an exceedingly high current consumption namely 130 kilowatt hours per million gallons, during most of the time two thirds of this consumption would be ample

The first application of the ultra violet ray system for sterilizing water on a large scale in this country was

Fig 15 —The pistol lamp

started recently in New York where the water of a swimming pool is continually being circulated through a rapid filter and a sterilizing flume equipped with two 220 volt pistol lamps the flow being about 5 000 gallons an hour

As mentioned in the theoretical part the ultra violet rays must be able to strike the microbe where any suspended matter is interposed the bactericidal action cannot take place because the microbe is in the shadow It is certain therefore that only clear water can be submitted to the ultra violet ray treatment for its sterilization That is to say in most cases it is necessary to filter the water before the same is submitted to the action of the lamps As color in solution will absorb ultra violet rays to a certain extent it is evidently better to also free the water from coloring material before submitting it to the rays

The question of suspended matter in the water is of somewhat greater importance Sometimes water with little suspended matter may be more difficult to sterilize than water with far more suspended matter The reason for this is that it will depend not only on the size and quantity of the suspended matter but also on its biological quality That is to say suspensions of purely mineral nature which do not inclose any microbes and to which few microbes are attached handicap the sterilization of the water very much less than suspended particles in similar water which are heavily covered with microbes and particularly so if microbes are inclosed in these particles because it is then most likely

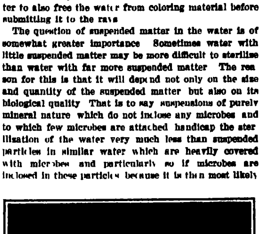


Fig 16.—Sterilizing apparatus at Luneville, France, in which ten pistol 500 volt lamps operate on one 1,500 000 gallons of water a day.

that a repeated exposure to the rays will be necessary to penetrate to the inclosed germ life

If the suspended matter is of smaller size than the germs like colloidal clay we expect such turbidity to act more or less like color in solution demanding simply more illumination than clear water Experiments made with one of the B2 apparatus on water showing up to 20 turbidity seem to prove that such fine turbidity does not handicap sterilization very much

From the economical point of view the condition in which the water is submitted to the rays is evidently of great importance for the ultra violet rays sterilization system Physically ideal water, that is to say, water without suspended matter, turbidity of color, will need very little power in ultra-violet rays to become sterile In large plants 50 kilowatt hours per million gallons will produce a great over-dose in ultra violet.

Smaller installations are being equipped usually with charcoal or paper filters. In large plants naturally the filter question is an engineering proposition, so is the question of choice between mechanical and sand filters

It seems that if the latter are chosen they can be speeded up to a great extent as against the speed for biological filtration and still give a physically pure enough water for ultra violet ray treatment as for example the Luneville plant where the water is filtered practically at three times the rate of biological filtration for that particular kind of water In other plants the filtration has been speeded up to 10 000,000 gallons to 12 000 000 gallons per acre, and we even tried with fair success 25 000 000 gallons per acre followed by ultra violet ray treatment. This will, naturally always depend on the filtrability of the water

Operating costs will vary with the size and the running hours of the plant, and the *coefficient of safety* one wants to give to the ultra violet ray treatment. According to the quality of the water I expect in large plants the current consumption will vary between 50 and 125 kilowatt hours per million gallons allowing for a large safety coefficient. The labor charges are negligible as the apparatus only needs an occasional cleaning and starting of lamps Apart from this, the lamps have to be repumped and repaired from time to time

In any engineering proposition we always try to adopt as large a *safety coefficient* as possible. If we rely on chemicals to disinfect our water we must work right close to and sometimes even over the limit of the amount which will not make itself objectionable by producing taste and odor in the water

In the ultra violet rays we have a system where we may choose *our safety coefficient as high as ever we liked* that is to say we may *over dose* our sterilization as much as we want without creating any objectionable features in the water like taste and odor

The Photokaleidograph*

An Apparatus for the Production of Kaleidoscopic Pictures

The kaleidoscope has not been used exclusively as a plaything for children. It has furnished many patterns for woven fabrics embroideries carpets and oilcloths The combination of the kaleidoscope with the photographic camera has often been attempted but with little success

In the last few years my attention has been drawn to these matters in the course of my professional work for the Carl Zeiss Optical Company We received a commission to construct a kaleidoscope of precision After overcoming certain difficulties I succeeded in producing the instrument herewith illustrated which can be used either for direct observation or for photographic reproduction of the kaleidoscopic patterns

In this instrument a solid glass prism takes the place of the two inclined mirrors of the old Brewster kaleidoscope The faces of the prism are cut accurately to the prescribed angle polished and silvered The prism is protected from injury by covering it with strips of black glass cemented to its faces The ends of the prism are cut perpendicular to the axis and polished and the prism is inclosed in a brass tube from which its ends only protrude

The tube is mounted vertically above the horizontal photographic plate measuring 13 by 18 centimeters (about 5 by 7 inches) The photographic lens is secured to the lower end of the tube. The distance of the tube from the photographic plate is adjusted to produce a sharp image and this distance is fixed by means of a stop-ring surrounding the tube Several tubes of exactly the same diameter containing prisms of different sizes and angles are provided and can easily be interchanged

The object, which is to produce the photographed kaleidoscopic pattern by internal reflection from the faces of the prism is itself a photograph on glass which is pressed lightly, with the film side down, on the upper end of the prism, to which a drop of oil has been applied. The picture is usually larger than the sectional area of the prism but only the part included in that area is reproduced and repeated on the photographic plate beneath The illumination is furnished by a mercury vapor lamp provided with a ray filter which transmits only the light of one of the violet mercury lines.

For the observation and selection of the patterns an inclined plane mirror is placed between the lens and the plate holder This mirror reflects the kaleidoscopic image to a ground glass screen which can be observed by several persons at once If it is decided to photograph the pattern, the mirror, which is mounted on a horizontal axis, is turned into a position in which it excludes light entering through the ground glass and allows the rays from the lens to fall on the photographic plate. The mirror is fastened in this position

* Translated from Dr Paltzsch's article in *Die Umschau*.

during the exposure of about one minute. It is then turned back to its former position in which it excludes all light from the plate and again reflects the image to

Fig 1—The Photokaleidograph

the ground glass (The entrance of light through the ground glass can also be prevented by closing a sliding shutter of sheet metal beneath the glass)

Details of the picture may be traced on the ground glass screen This device is often useful for the purpose of combining several kaleidoscopic pictures A great variety of photographic transparencies may be used as objects but photographs of other kaleidoscopic patterns are especially suitable

Each of the prisms can also be used for the direct observation of kaleidoscopic combinations For this purpose a special observing lens is substituted for the camera lens The other end of the tube is fitted into a base so that the prism can stand erect on a table over a drawing which is illuminated by light entering the prism laterally from above

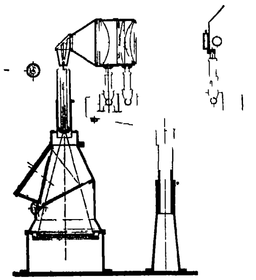

Fig 2—Diagram of the photokaleidograph

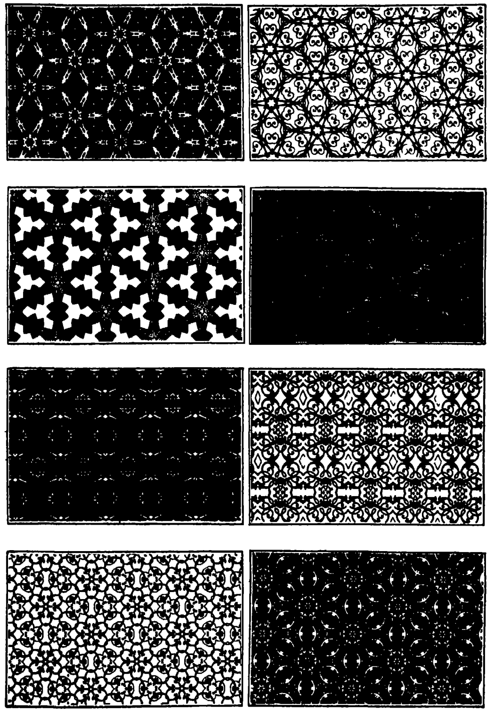

Fig 3—Photographs of kaleidoscopic patterns

The Stars Around the North Pole*

The Determination of Their Proper and Irregular Motions

A KNOWLEDGE of distances of the stars is of fundamental importance in any attempt to describe the stellar universe It is required before answers can be given to questions on the average distances of stars from one another their brightness compared with the sun, and the extent to which they reach in space There are not more than 100 or 150 stars of which the distances have been measured with any degree of accuracy Although this number is being steadily increased it is only the stars which are comparatively near to the sun which can be treated individually For the greater number we have to be content with average values which apply to groups of stars

A map or a photograph of the stars gives only their bearings, that is to say their directions as seen from the earth It gives no information whatever about the distances. One star may be a hundred times as far away as its neighbor on the map But if two maps are made, separated by a sufficient interval of time, some differences will be found in the relative positions of the stars. These indicate movements either of the stars themselves or of the point from which they are viewed But the movements which are observed are merely changes of angular position We cannot tell directly from them either the actual velocities or distances of the stars but only the ratio between these quantities It is however from the geometrical study of these small angular motions supplemented by the information obtained from the spectroscope as to the velocities of stars in the line of sight that our knowledge of their distances is derived

The problem is in many ways analogous to one which has been completely solved In the early days of astronomy the movements of the wandering stars or planets were noted. The essential characteristics of the movements were embodied in geometrical formulæ by the Greeks In the course of time Copernicus showed that these formulæ could be most simply interpreted on the assumption that the earth revolved around the sun His purely geometrical arguments were it is true powerfully reinforced by the revelations of Galileo's telescope Nevertheless the planetary system as formulated by Copernicus and Kepler resulted from the observation of the angular movements of the planets and the attempt to give them the simplest possible geometrical interpretation

Further study of the planetary system has been guided and controlled by the law of gravitation But the observational data on which our very complete knowledge of the solar system is based the distances sizes, and movements of all its members are a long series of measures of the angular movements as seen from the earth Linear measurements are only required to obtain the form and dimensions of the earth itself and thus supply a base line to determine the scale of the system

The fixed stars present us with a very similar problem From the study of their small angular movements supplemented by spectroscopic observations it is required to construct as far as possible a model of the stellar universe Such a model would give for each star

(1) Its actual position in space measured along three axes with the sun as origin

(2) The velocity in kilometers a second in each of these directions

(3) The brightness or luminosity taking the sun as unit

(4) The mass

(5) The size.

(6) The physical and chemical constitution

Of these elements the mass is at present only determinable for double stars and the size for eclipsing

* An address delivered at the Royal Institution by Dr F W. Dyson, F.R.S.

variables The physical and chemical constitution are known from spectroscopic observations for a considerable number of stars But the distance and absolute brightness can be found only for a limited number of the nearest stars Average results can however be

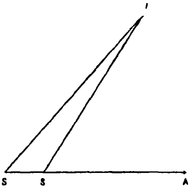

Fig 1—Determining proper motion of stars

obtained for the more distant stars which tell us

(1) The number within certain limits of distance from the sun

(2) The mean velocities of these stars and what percentage are moving with given velocities say for example between 10 and 20 kilometers a second

(3) Whether these velocities are irregular or show anything in the nature of streaming in particular directions

(4) What proportion of the stars are comparable with the sun in intrinsic brightness and what proportion are ten times or one tenth as bright and so on

Such a description of the stellar system is to a large extent within the powers of astronomers and we nurse the perhaps extravagant hope that generalizations will be discovered which will lead to the formulation of dynamical laws on the constitution of the stellar universe

A small area round the pole has been chosen as a sample because this part of the sky has been observed more fully than any other of equal extent It forms a small cap extending to a distance of 9 degrees from the pole and covering about 1/160 of the whole sky In the year 1855-1856 Carrington an English amateur astronomer well known from his observations of sun spots using a very small transit instrument observed the positions of all the stars in this part of the sky from the brightest down to very faint stars between the tenth and eleventh magnitudes He thus constructed a catalogue giving with great accuracy the positions of 3 700 stars for the year 1855 About the year 1900 these stars were re observed at Greenwich by a combination of visual and photographic observations By comparison with the positions as given in Carrington's Catalogue the angular movement of each of these 3 700 stars in forty five years is determined These angular movements or proper motions as they are technically called are the data available for obtaining the actual positions and movements of the stars in space We have to solve the geometrical problem of making these stars stand out in three dimensions so that we may see them as we see a picture in a stereoscope

Now the proper motions of stars are very small The star of largest proper motion moves only 870 seconds a century An idea of the smallness of this motion may be obtained from the fact that it will take two centuries to move a distance equal to the apparent diameter of the sun or moon There is no star among those near the north pole with a proper motion so great as this The following table gives an abstract of the proper motions of the 3 726 stars under consideration

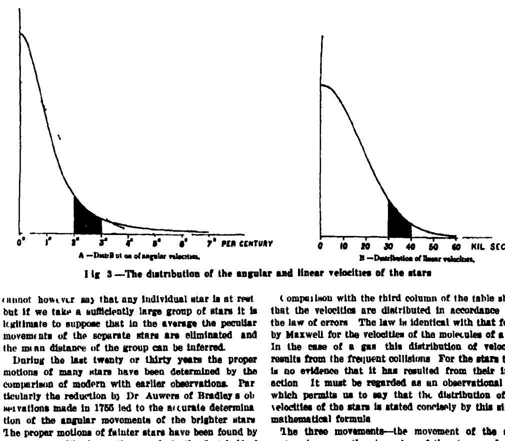
TABLE I

Limits of Proper Motion	Number of Stars
>40′ a century	2
20′—40′	39
10—20	134
5—10′	574
3—5	977
0′—3	2 000

It is clear that the stars with large proper motions must either be moving fast or must be comparatively near These are the alternatives but for an individual star it is impossible to decide between them

The table shows how largely the proper motions of stars vary in direction They differ just as widely in direction Some signs of irregularity in the directions were first detected by Sir William Herschel, who found that the movement of seven quick moving stars situated in different parts of the sky were approximately directed to one point. He observed that this would result if the proper motions arose not from the movement of the stars themselves but from that of the point of observation in an opposite direction, and concluded that the solar system was moving toward a point in the constellation Hercules This conclusion was not universally admitted for some time but researches by Argelander Airy Bessel and others demonstrated a regular drift among the stars such as would arise if on their otherwise irregular movements were superposed this common motion A large number of researches have been made on the exact direction of the sun's motion and it is now established with some certainty that it is toward a point in right ascension 18 hours and declination 35 degrees north not far in direction from the bright star Vega The speed of the sun's motion through space has been determined by spectroscopic observations On the average stars near Vega appear to be approaching us stars in the opposite direction to be receding from us In this way Prof Campbell has found from the observed velocities of 1,500 stars that the solar system is moving at the rate of 19 6 kilometers a second

The fact that the sun is moving with a velocity of 19 5 kilometers a second in a known direction supplies us with a means of determining the average distances of groups of stars This velocity carries the sun forward in a century a distance equal to 412 times the sun's distance from the earth If at the beginning of the century the sun is at S (Fig 1) and at the end has moved to S the angular distance of a star situated at P and having no motion of its own will have increased from ASP to ASP The difference of these angles which is the proper motion of the star is SPS and it follows that the distance (SP) can readily be deduced We



A —Distribution of angular velocities, B —Distribution of linear velocities,

Fig 3—The distribution of the angular and linear velocities of the stars

cannot however say that any individual star is at rest but if we take a sufficiently large group of stars it is legitimate to suppose that in the average the peculiar movements of the separate stars are eliminated and the mean distance of the group can be inferred.

During the last twenty or thirty years the proper motions of many stars have been determined by the comparison of modern with earlier observations. Particularly the reduction by Dr Auwers of Bradley's observations made in 1755 led to the accurate determination of the angular movements of the brighter stars The proper motions of fainter stars have been found by comparison with observations made in the first half of the nineteenth century These have all been utilised to determine the direction and angular amount of the drift produced in the stars by the motion of the solar system through space The results were very puzzling because different mathematical methods and different groups of stars gave widely different directions for the solar motion The cause was discovered about ten years ago by Prof Kapteyn who found in the proper motions of the stars another indication of regularity, or perhaps it might be called a systematic irregularity smaller than the one discovered by Herschel, but unmistakable when once pointed out. He interpreted these systematic irregularities to mean that the stars are divisible into two groups streaming through one another in opposite directions in space Prof Kapteyn's discovery has been submitted to mathematical analysis by Prof Eddington and Prof. Schwarzschild Their researches have illuminated the whole subject of stellar motions, and though they are not in entire agreement, they leave no doubt of the existence of a preferential movement among the stars toward the north part of Orion and the diametrically opposite direction in the constellation of the Serpent.

We must next consider the *motus peculiares*—the irregular movements of the stars themselves. From observations of the velocities of stars in the line of sight, especially from those made at the Lick Observatory under Prof Campbell's direction, it is known that a few stars are moving with great velocities, such as 100 kilometers a second, while others are moving very slowly The following analysis of Campbell's results for one class of stars—those of spectral type A—(taken from a paper by Prof Eddington) shows the proportion of slow moving moderate, and quick moving stars

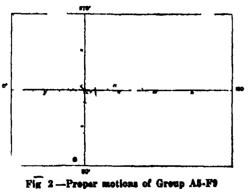


Fig 2—Proper motions of Group A5-F9

TABLE II

Velocities	Number of Stars observed	Number of Stars given by error law
0—5 kil/sec	55	53 4
5—10	47	46 2
10—15	30	38 3
15—25	30	27 4
25—40	10	6 7
>40	0	0

Comparison with the third column of the table shows that the velocities are distributed in accordance with the law of errors The law is identical with that found by Maxwell for the velocities of the molecules of a gas In the case of a gas this distribution of velocities results from the frequent collisions For the stars there is no evidence that it has resulted from their interaction It must be regarded as an observational fact which permits us to say that the distribution of the velocities of the stars is stated concisely by this simple mathematical formula

The three movements—the movement of the solar system in space the streaming of the stars, and their irregular movements are all shown in their proper motions. The figure (taken from a paper by Mr Jones

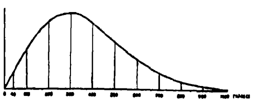

Fig 4—Distribution in distance of the star in Carrington's catalogue.

—Monthly Notices of the R A S, vol lxxiv, p 196) exhibits the proper motions of some of the brighter stars situated near the north pole If the stars had all been placed at the origin they would in a century have spread out as shown in the figure

This spreading out has been caused by

(1) The solar motion which has shifted the center of gravity of the swarm toward 180 degrees

(2) The peculiar motions of the stars themselves, which have spread out in the directions toward 90 degrees and 270 degrees.

(3) The streaming in the direction of 0 degree to 180 degrees, which, combined with the peculiar motions, has made the spreading out much greater in this than in the perpendicular direction. In this part of the sky the

streaming happens to be in the direction of and opposite to the solar motion.

Let us now consider the proper motions of the 3,700 stars observed by Carrington in the light of these discoveries. The shift of the center of gravity caused by the solar motion is 1.44 seconds a century. As we know how far the sun has moved in a century, this gives the average distance of these stars as fifty million times the distance of the sun from the earth. Turning now to the proper motions in a direction perpendicular to that of the sun's motion, which arise from the *motus peculiares* of the stars themselves. Counting these cross proper motions we find them divided as shown in Table III.

TABLE III

16 are greater than	1".0	a century	
35 lie between	10.0	and	10.0 a century
33	8.0		10.0
66	6.0		8.0
191	4.0		6.0
873	2.0		4.0
2504	0.0		2.0

When suitable allowance is made for the accidental error in these observations, it is found that the number less than any given amount τ can be represented by the following algebraical formula

$$3700 \frac{\tau}{\sqrt{(\tau^2 + 1.17^2)}}$$

The distribution of the angular velocities is shown in Fig. 3 (A); the total number being represented by the area of the curve, the number, for example, between 2 seconds and 3 seconds a century is given by the shaded portion.

Now suppose that all these stars were actually moving with the same velocity, say 10 kilometers a second, then their distance could be calculated: those with proper motion 1 second a century being forty million times as distant as the sun, those with proper motion 2 seconds a century twenty million times, those of 4 seconds a century ten million times, and so on, the larger the proper motion the nearer the star to us.

This is only an illustration; the velocities of the stars are not all the same, but are distributed according to the law of errors. If the distance of each star were known, then by dividing the velocity by the distance the proper motion would be found. We have to find how many are at one distance, how many at another, so that the proper motions will be distributed in accordance with the law found from the observations.

Fig. 3 (B) shows the distribution of linear velocities, the shaded portion, for example, giving the proportion moving between 30 and 40 kilometers a second. Now the distribution of angular velocities is shown in (A), and the question arises: How must the stars be distributed in distance for these two laws to harmonize?

This is a mathematical problem which can be solved fairly easily, and the answer is that the stars must be distributed in distance according to a law shown graphically by the curve in Fig. 4. (The distribution of velocities $\frac{h}{\sqrt{\pi}} e^{-h^2v^2}\,dv$ combined with the distribution of proper motions $\frac{dr}{a}\left(1 + \frac{r^2}{a^2}\right)^{-\frac{3}{2}}$ leads to the partial distribution $2a^2h^3r^2 e^{-h^2r^2}dr$.)

In the diagram distances are measured horizontally, the unit of distance being that at which a star's parallax is equal to 1 second (or 206,265 times the distance of the earth from the sun). It is convenient to have a name for this unit, and in what follows the word *Parsec*, suggested by Prof. Turner, will be adopted. With this unit a distance of 100 in the diagram denotes twenty million times the distance of the sun from the earth. The following table gives the percentage of stars between certain limits of distance.

TABLE IV

6	per cent of the stars are between	0	and 100	parsecs
5		100	200	
10		200	400	
45		400	700	
35			>700	

It follows that 58 per cent of the stars in Carrington's Catalogue, that is, 58 per cent of all the stars brighter than about 10.5 magnitude, lie between 20 and 150 million times the distance of the sun from the earth. This law of the distribution of the stars is at first sight rather surprising. It should be remembered that the only stars at a great distance which are included are those which are intrinsically very bright, and these form only a small proportion of all the stars. Prof. Eddington has found that a similar law holds for stars brighter than 6.0 magnitude.

Having found the law of distribution of the distances of these stars, it is not difficult to determine something about their absolute luminosities, i. e., how they would compare with the sun in brightness if placed at an equal distance from us.

If the sun were at a distance of one *parsec*, it would appear as a bright star, brighter than the first magnitude—actually of magnitude 0.5; if at a distance of 100 parsecs, its magnitude would be 10.5. Now all the stars in Carrington's Catalogue may be taken as brighter than 10.5 magnitude, thus at least 95 per cent of these stars are intrinsically brighter than the sun, and at least 80 per cent are four times as bright, 40 per cent are sixteen times as bright and 8 per cent are fifty times as bright.

We may conclude that the great majority of the stars brighter than 10.5 magnitude are intrinsically brighter than the sun and a considerable proportion very much brighter.

The distribution of bright and faint stars in a given volume of space is quite different and contains a much larger proportion of faint stars. If we make the assumptions that the density of the stars and the proportions of bright and faint ones is the same at the different distances from the sun within which these Carrington stars are situated, it is possible to find the actual number of stars of different luminosities in a given volume of space. In a sphere with radius 100 parsecs, or twenty million times the distance of the earth from the sun there are at least

24	whose luminosity is	100 times as luminous as the sun
340		50
1,530		5
4,840		10
23,200		1
91,100		1/10th the luminosity of the sun

The data only admit of a rough determination of the number of very faint stars and the number of very bright ones. The figures give a general indication of the density of the stars in space and of their intrinsic brightness and serve to direct attention to the fact that there are many stars much less luminous than the sun and a certain proportion very much more luminous.

The conclusions drawn up to this point have been based entirely on a consideration of the proper motions of the stars irrespective of whether they are bright or faint, provided only that they are sufficiently bright to have been observed by Carrington. But as the apparent magnitude of a star depends on its distance as well as on its intrinsic brightness, we naturally expect some assistance in assigning the distances of these stars from their magnitudes. The brightest star in this small area round the north pole is Polaris, the magnitude of which is 2. (It may be remarked incidentally that the distance of the pole star has been actually measured. It is twenty parsecs or four million times the distance of the sun from the earth, and if it were at the same distance as the sun it would appear to be 100 times as bright.) Then there are about twenty stars which are visible to the naked eye. The following table gives the actual number of stars of different magnitudes (photographic):

TABLE V

Brighter than	7.0m	11 stars
From 7.0m to	8.0m	14
8.0m	9.0m	49
9.0m	10.0m	905
Fainter than	10.0m	140

Then again the stars may be divided into groups according to the physical characteristics revealed by the spectroscope. The researches of Kapteyn, Campbell and others have shown—at any rate for the brighter stars—remarkable relationships between the distances and velocities of the stars and the type of spectrum which they manifest. It is therefore desirable to examine the proper motions of stars of different spectral types separately. The spectra of many thousands of stars have been determined at Harvard College under Prof. Pickering's direction by Miss Cannon. The different classes are indicated in the Harvard classification by the letters B, A, F, G, K, M, with further subdivisions. The B stars are characterized by the presence of helium, the A stars by series of broad hydrogen lines. In the F stars the hydrogen lines are thinner and fine metallic lines are shown. The G stars are very like the sun, full of metallic lines and with broad lines due to calcium. In the K stars the two calcium lines are still broader and there are many fine metallic lines. The M stars are characterised by broad absorption bands. This arrangement places the stars in the order of their temperatures, the B stars are the bluest and hottest, and the M stars the reddest and coolest. The character of the spectra of about 800 of the stars in Carrington's Catalogue is given by the Harvard observations.

For the fainter stars the spectra have not been determined, but they can be inferred in another way. As the blue stars are more active photographically than the red stars, if a red and blue star have the same visual magnitude the magnitudes estimated from the images on a photograph will differ considerably, and this difference is an index of the color and thus of the type of spectrum. Now the visual magnitudes of most of these faint stars have been very accurately determined at Potsdam by Messrs. Müller and Kron (and have been kindly communicated in manuscript) and the photographic magnitudes have been determined at Greenwich. The differences have been taken between the photographic and visual magnitudes and serve to classify the stars according to their temperature.

Separating the stars into two groups, those which are brighter than 9.5 magnitude on the Potsdam scale of magnitude, and dividing each group into four classes according to the color index, the parallactic motion, i. e., the mean angular movement per century arising from the motion of the sun through space, is determined for each class. The results are exhibited in the following table.

TABLE VI

Spectral Class	Color Index	Stars brighter than 9.5 Number	Stars brighter than 9.5 Parallactic motion	Stars fainter than 9.5 Number	Stars fainter than 9.5 Parallactic motion
K, M	>.8	1	0.0	60	0.38
K	.4 .8	105	1.31	428	0.95
F, G	.1 .4	54	3.8	959	1.53
A, F	< .1	240	1.97	460	1.28

In this table the red stars are on the top line, the third line consists of stars which are in the same stage of development as the sun, those in the second line are somewhat cooler and redder, those in the last line hotter and bluer. The last line includes a few, but only a few, B stars, as there are not many in this part of the sky. The quantities in the fourth and sixth columns of the table are a gage of the distance of the stars to which they refer. It is only necessary to divide these into 3.7 seconds, which is the angle through which a star distant 1 parsec would have been displaced in the solar motion in one hundred years, to obtain the distances in parsecs. Thus the 240 stars belonging to types A, F and brighter than 9.5 magnitude are at an average distance of 170 parsecs.

The first point to notice is that *parallactic motions of stars fainter than 9.5 magnitude are always considerably less than the corresponding quantities for stars brighter than 9.5 magnitude.* This is of course because the faint stars are on the whole further away. The average distance of stars of magnitude 10.0 is approximately 1½ times as great as for a star of 8.0 magnitude.

The next point is the very great distance of the red stars. The 59 faint red stars are very nearly 1,000 parsecs away or 200 million times as distant as the sun. At this great distance the sun would appear as of magnitude 15.5, but these stars vary in magnitude from 9.5 to 11.0 and are therefore intrinsically from 250 to 63 times as bright as the sun. Now it happens that among the stars nearest to the sun the distances of which have been actually measured there are several red stars and these are all very much fainter than the sun. It has been suggested by Prof. Russell and Prof. Hertzsprung independently that the red stars are of two distinct classes, which they call the giants and the dwarfs, and that in accordance with Sir Norman Lockyer's views the giant red stars are in an early stage of evolution and are increasing in temperature, while the dwarf stars are at the other end of the series and are growing colder and darker.

Leaving the red stars, it is seen that the stars the color indexes of which lie between —1 and +4 are nearer to us than the groups on either side of them. These stars are those the spectra of which are of the types F and G in the Harvard notation and are the stars most like the sun. The mean distances of these stars is only 130 parsecs for the stars brighter than 9.5 magnitude and 215 parsecs for the stars fainter than 9.5 magnitude. At this distance the sun would be of magnitude 12.1. It follows that these stars are on the average from two to eight times as bright as the sun. The A, F stars are a little but not much farther away, the stars fainter than 9.5 magnitude being at an average distance of 263 parsecs. At this distance the sun would have a magnitude of 12.5, and these stars are from sixteen to four times as luminous as the sun.

It has been shown how the knowledge that the solar system is moving in a known direction with a velocity of 19.5 kilometers per second leads to a determination of the distances of groups of stars the angular movements of which are known. The hypothesis made is that in a number like one hundred or two hundred stars the irregular angular movements due to the motions of the stars themselves neutralize one another on the average. But this is only the mean distance of the group, and some are much nearer and some much farther. The distribution of the stars about this mean distance may be derived from the proper motions if we know how the linear velocities are distributed. I shall apply this method to the group of stars which are like the sun in type of spectrum and therefore presumably of like temperature and physical constitution.

Dividing these into three classes according to their magnitude, it is found that their parallactic motion due to the sun's movement and their average motion in the perpendicular direction due to their own peculiar movements are as follows:

	N	Parallactic motion	Av. cross motion	Ratio
All stars down to 11.0m	1,247	1.92	±1.67	0.87
Stars brighter than 10.0m	470	2.80	+2.10	0.84
Stars brighter than 9.0m	148	3.34	+2.90	0.87

In the last column is given the ratio of the average cross motion to the parallactic motion The agreement of the numbers shows that the bright stars and the faint stars have the same average velocity. Taking the velocity of the sun as 19 5 kilometers a second, it follows that the average velocity of these stars in the direction perpendicular to the sun's motion is 13 7 kilometers a second

We shall now make the assumption that some of these stars are moving faster than this velocity and some slower, just as errors of observation are distributed about a mean error With a mean velocity of 13 7 kilometers a second, there will be in 1,000 stars

211	with velocities	0 to	5 km/sec
208	"	5 "	10
175	"	10 "	15
141	"	15 "	20
103	"	20 "	30
59	"	30 "	40
18	"	40 "	50
1	"		>50

If now the observed proper motions are arranged, it is found that the number less than any value τ can be represented satisfactorily by an algebraic formula

$$N \frac{\tau}{(\tau^2 + a^2)^{\frac{1}{2}}}$$

mean value of τ. The following table shows the actual number of stars with proper motions between certain limits, compared with the number given by the formula:

TABLE VII

Limits of proper motion	No of stars observed	No given by formula	Difference
0″ to 1″ a century	427	429	−2
1 " 2 "	346	337	+9
2 " 4 "	324	332	−8
4 " 7 "	105	103	+2
7 " 10 "	25	22	+3
>10 "	20	19	+1

We may take it that the formula substantially represents the observed facts With the proper motions distributed according to this formula, and the actual velocities distributed according to the law of errors, the distribution of the stars in distance can be determined, and it is found that these 1,247 stars are distributed in space as shown in Table VIII.

TABLE VIII.

NUMBER OF SOLAR STARS (TYPES F AND G) AT DIFFERENT DISTANCES.

Distance (parsecs)	Out of total 1,247 stars	Out of 470 stars brighter than 10.0m	Out of 148 stars brighter than 9.0m
<100	121	76	40
100—200	298	101	65
200—300	332	136	34
300—400	254	68	8
400—500	146	23	1
500—600	65	5	
600—700	25		
>700	5		

The most remarkable feature of this table is that 70 per cent of the stars lie between the narrow limits of one hundred and four hundred parsecs.

I have treated the 470 stars which are brighter than 10.0 magnitude and the 148 brighter than 9.0 magnitude in a similar manner. The results are given in the third and fourth columns of Table VIII. Taking the differences, the distribution in distance of the 777 stars of magnitude is 10.0-11.0 and of the 322 stars of 9 0-10.0 magnitude is found.

To compare the intrinsic magnitudes of the stars it is convenient to take limits of distance in geometrical progression with a common ratio 1 259 (log = 0.1), e g, 40, 50, 63, 79, 100, 126, etc., parsecs. These limits correspond to a change of half a magnitude in the intrinsic brightness of the stars which are of the same apparent brightness. Confining our attention to the stars of apparent magnitude 10 0 to 11 0, or, speaking broadly, stars of 10 5 magnitude, the limits 50-63 parsecs contain stars half a magnitude brighter, and distributed over twice the volume of those contained between the limits 40 50 parsecs

If we may assume that the actual density of the stars is the same in all parts of the space with which we are dealing, we obtain by reasoning of this kind the number of stars between different limits of absolute brightness The following table shows the number of stars of different luminosities in a sphere of one hundred parsecs radius

Luminosity =1	No of stars 10 0m – 11 0m	No of stars 9 0m – 10 0m
0 40 to 1 0	16 000	18 000
1 0 " 2 5	9 500	11 300
2 5 " 6 3	5 700	7 100
6 3 " 16	2 570	3 600
16 " 40	302	1 040
Brighter than 40	14	68

The results in the second column have been obtained by considering the faintest stars, those from 10 0 to 11.0 magnitude If the class brighter is taken, those stars which appear to be of magnitudes 9 0 to 10.0, we find in a similar way the quantities given in the last column.

There is an increasing divergence between the results. Now it is to be remembered that these figures have been derived from regions at different distances from the sun. Thus the stars which are between sixty and forty times the brightness of the sun, and which are apparently of magnitude 10 to 11, lie between 398 and 631 parsecs, while those which are apparently of 9.0 to 10.0 magnitude lie between 251 and 398 parsecs.

We may conclude, therefore, that the density of this *class of stars is somewhat less at this greater distance* from the sun. Following out this line of reasoning, I have found the diminution of density of the stars to be as follows:

Distance	Density	Distance	Density
At 50 parsecs	1 30	At 300 parsecs	0 48
" 100 "	1 00	" 400 "	0 32
" 200 "	0 70	" 500 "	0 21

Although much weight cannot be attached to the exact figures, one seems justified in saying that there must be a very considerable falling off in the density of the stars between the distances of 100 and 500 parsecs A falling off in the total density of the stars would affect the tables giving the proportion of stars of different brightness, and would increase considerably the proportion of bright stars.

Although the conclusions presented in this paper have been derived from a study of the proper motions of the stars in a small area of the sky, and may be somewhat modified by the investigation of other regions, they may be considered as fairly applicable to the stars in general. The limiting magnitude of the stars that have been considered is nearly 11.0 (on the Potsdam scale), and there are, in the whole sky, half a million stars brighter than this limit of magnitude.

It may be said of them that:

(1) On the whole, the yellow stars, the stars like the sun in physical conditions, are the nearest.

(2) They lie within fairly narrow limits of distance —80 per cent are between 100 and 500 parsecs, 10 per cent nearer than 100 parsecs, and 10 per cent farther away than 500 parsecs.

(3) Going from the yellow to the blue or the orange stars, the average distances increase.

(4) The red stars are at great distances—an average of about 1,000 parsecs.

(5) The stars vary greatly in *intrinsic brightness*. The red stars are specially luminous, being on an average one hundred times as bright as the sun.

(6) Considering all the stars down to this limit of magnitude, from 90 to 95 per cent are intrinsically more luminous than the sun.

(7) When, however, the luminosity of the stars in a given volume of space is considered, there are found to be far more faint than bright stars. There is no contradiction between this conclusion and the last one, because the more distant bright stars are visible, while we only see the faint ones which are comparatively near.

(8) Evidence has been found that the stars thin out very materially at great distances from the sun

These conclusions are in harmony with the conception of a finite stellar universe. Most of the stars we see, and a great many fainter ones, are within the distance of 1,000 parsecs Doubtless the stars extend to much greater distances, perhaps ten times as far or farther, but we can scarcely doubt that we are near the middle of a finite group of stars, and that the extent of this group is of the order of 1,000 to 10,000 parsecs

Another System of Generating Electricity

ONE of the latest propositions for producing electricity commercially is the application of thermo-electric couples placed around a heated flue. These couples are composed of an element made of a special alloy and a copper-nickel element. These elements are separated by a layer of mica insulation and are joined together at their hot ends by a band of electrolytically deposited copper. Five of these elements are connected together in series to form a unit, and a suitable number of these units, which are wedge shaped, are formed into a ring that surrounds the heated flue, from which it is insulated by an interposed layer of mica to prevent short circuiting the units. The unheated ends of the elements are kept cool by circulating cold air around them. It is said that the cost of installing such a system, as compared with steam, gas and oil operated engines, is as 13 compared to 26, 30 and 38, respectively, while the cost of producing electricity by this arrangement compares with the above sources as 5.6 to 24, 16.5 and 19.3, respectively, not taking into consideration the cost of depreciation or attendance of the steam, gas and oil plants.

Dr. Bose's Visit to America

PROF. J. C. BOSE, whose discoveries regarding the continuity of physiological response in the plant and animal created great interest in England and the Continent, is now in America on scientific mission from the British government. Prof. Bose will exhibit his resonant recorder at Philadelphia before Section G of the American Association for Advancement of Science on the 29th of December. This instrument records time intervals as short as the thousandth part of a second, and measures the perception time of a plant. On the 11th of January Prof. Bose will give a discourse on "Plant Autographs and Their Revelations," illustrated by original experiments, before the Academy of Sciences, New York. Before his return to Europe Dr. Bose will lecture before the Columbia University, the Academy of Sciences, Washington; the Philosophical Society of Philadelphia, the Twentieth Century Club, Boston; the Universities of Chicago, Wisconsin, Illinois, and Michigan.

Locomotive Headlights

IT is stated by an authority on the subject, that the intensity of the head-light of a locomotive should not be greater than fifteen to twenty candle power per square inch of its projected area, hence a lamp of 3,000 candle power, with a 16-inch reflector, will give an illumination within the maximum limit. The chief function of a head-light is to warn persons ahead of the approach of the train, as no commercially practical light would enable the engineer to see a dark object, like a man, more than 500 feet. The light, however, serves as a warning in many cases at a distance of 25 miles, and it is also useful to the engineer in distinguishing landmarks, whistle boards and similar objects.

SCIENTIFIC AMERICAN SUPPLEMENT

Founded 1876

NEW YORK, SATURDAY, JANUARY 2, 1915

Published weekly by Munn & Company, Incorporated
Charles Allen Munn, President; Frederick Converse Beach, Secretary; Orson D. Munn, Treasurer
all at 361 Broadway, New York

Entered at Post Office of New York, N. Y., as Second Class Matter

The Scientific American Publications

Scientific American Supplement (established 1876) per year $5.00
Scientific American (established 1845) . . . . " 3 00
American Homes and Gardens . . . . " 3.00
The combined subscription rates and rates to foreign countries, including Canada, will be furnished upon application
Remit by postal or express money order, bank draft or check

Munn & Co., Inc., 361 Broadway, New York

The purpose of the Supplement is to publish the more important announcements of distinguished technologists, to digest significant articles that appear in European publications, and altogether to reflect the most advanced thought in science and industry throughout the world.

Experiments in Hybridizing Japanese Flowers

Which Appear to Show a Variation in Mendel's Law

By Walter Proctor Jenny, Ph.D.

The results of these experiments in hybridization are due to the discovery made early in the progress of the work, *that the dry pollen of the white moonflower, applied to the stigma of the morning glory, is inert and will not fertilize the ovary, unless the pollen be wet with the dew-like fluid excreted upon the surface of the stigma of the moonflower.*

The purpose of this article is to place upon record the results of experiments conducted for a term of years, at private expense, at my home in the city of Washington, D. C., an investigation undertaken and carried out owing to my interest in plant breeding—an interest stimulated by the fascination that attends the creation of new and beautiful flowers.

The method followed departs so widely from the usual procedure in hybridizing, and the results obtained are so exceptional, and offer such broad as well as important possibilities in the creation of new types, *that they can scarcely fail to prove of interest to other workers in this field.*

That the natural stigmal fluid of the moonflower, namely, the dew-like excretion deposited upon the surface of the stigma, when in readiness for self-fertilization, is also essential to the development of its pollen in the fertilization of the ovary of the morning glory, was discovered in this way. In my first attempts, I removed the anthers from the flowers of the morning glory, and then applied the pollen of the moonflower, using the reflexed flower as a brush. Some twenty-five flowers were thus pollenated, but only one produced seed. In the following season, 1912, I pollenated nearly 200 flowers of the morning glory, applying the pollen of the moonflower in different ways, without obtaining seed in a single instance; this was before I found that *the stigmal fluid of the moonflower was needed in order that fertilization of the ovary might take place.* In attempting to reverse the process and pollenate the moonflower with the pollen of the morning glory, I noticed the way in which the pollen grains adhered to the moist stigma of the moonflower, and with only the thought to make the pollen adhere more perfectly, I tried the experiment of transferring this excretion of the stigma to the stigma of the morning glory before applying the pollen of the moonflower. Several flowers of the morning glory were depollenated, and the stigmal fluid, together with the pollen of the moonflower, applied. A few days later, on examining these hybridized flowers, it was seen that fully one half of the flowers had commenced to develop seed. From this time on, the stigmal fluid of the moonflower was employed in all experiments in crossing these flowers.

The flowers experimented with are of different genera of *Convolvulaceæ*, namely,

1. "The early blooming white moonflower," *Calonyction speciosum*, with black seed, said to be a cross between *C. Mexicana alba* and *C. grandiflora alba*; it has been in cultivation a number of years; and

2. Numerous varieties of the Japanese morning glory, *Ipomœa Chinensis*, having flowers in many shades of red, rose, lilac, violet, purple, and blue, and also pure white.

Natural hybrids of the white moonflower and the morning glory do not appear to take place. I have, however, observed that the Japanese morning glory and the American morning glory will occasionally cross, where growing near to one another.

The flowers were grown in 12 to 14-inch pots, in the open air; the veins being trained upon trellises of bamboo and wire.

In the following statement, no attempt is made to give particular instructions to be followed, but rather to set forth what was done to produce the hybrid Ipomœa I have named *Bansai*.

All hybridizations that produced seed were made with the white moonflower as the male parent and the Japanese morning glory as the female. A number of attempts were made to reverse the process, applying the pollen of the morning glory to the stigma of the moonflower; but all failed to set seed. All hybrids and cross-bred plants described produced fertile seed.

The morning glory blooms in the early morning, often before daylight, while the moonflower blooms soon after sunset; so that to obtain a supply of moonflowers for hybridizing, it is usually necessary to gather the flowers soon after they open, and before they have been visited by insects, and to preserve them in shallow dishes of water in an ice chest. Where no insects are present the moonflowers may be let to remain on the vine and to be picked at early dawn, at the time the hybridization is performed. In my experiments no risks of insect interference have been allowed.

The flower selected *for the female parent has first* its pollen removed by the application of a fine stream of water—the excess of water is drained out and the flower dried by gently applying slender slips of blotting paper (following the method published by Mr. George Oliver, Department of Agriculture, Washington, D. C.).

I perform the hybridization as follows: I take a moonflower, reflex the flower and pull off the stamens, leaving the stigma intact. The stigma of the moonflower is then applied to the stigma of the morning glory, gently rubbing them one upon the other, so as to transfer the dew-like moisture upon the moonflower stigma to the stigma of the morning glory. This is repeated two or three times, using a fresh moonflower for each application. Then select a moonflower with ripe pollen, reflex the flower and holding it so that *the stamens are loosely bunched together*, insert the stamens in the tube of the morning glory, with the stigma of the morning glory in the midst of the anthers that is, the stigma of the morning glory is surrounded on all sides by the anthers of the moonflower; a slight movement, in and out of the stamens, at the same time rotating the moonflower, transfers the pollen to the wet stigma of the morning glory, to which it adheres. This application of pollen is repeated with one or more fresh moonflowers. The flower is then closed (like an unopened bud) and tied at the tip with yarn, to exclude insects—about 40 per cent of the flowers thus hybridized produce seed.

Sometimes I vary this method by first wetting the stigma of the morning glory with the vitalizing fluid of the moonflower and then alternately applying the anthers and the stigma of the moonflower, gently rubbing in the pollen with successive applications of the stigmas of fresh moonflowers, until the stigma of the morning glory is loaded with the adhesive coating of pollen.

The first hybrid that I obtained was Bansai, a flower of rare beauty, with a deep carmine center, margined by pure white. It was at once recognized as constituting a new type; of vigorous growth, and what was most important, the flowers had good keeping quality and did not wilt or change color, if shielded from the sun, even in the heat of summer. The great drawback with all morning glories, both Japanese and American, is the lack of permanence in the flowers, which either wilt or change color soon after sunrise.

Bansai was produced as follows: In the summer of 1911, *a red Japanese morning glory was selected as* the female parent and hybridized with the pollen of the white moonflower, as follows: the flower was depollenated and the pollen of the moonflower applied by employing the reflexed flower as a brush. It is supposed that in this solitary instance, some of the stigmal fluid of the moonflower was transferred in the process of pollenation to the stigma of the morning glory. This hybridization was made more than a year prior to the discovery that the stigmal fluid was essential to the development of the pollen in the fertilization of the ovary. As stated, only a single flower thus pollenated produced seed. In 1912 this seed was planted in a flower pot (12 inches in diameter) and early in July the new hybrid bloomed, and its self-pollenated seed was saved. A few flowers of Bansai, as an experiment, were again crossed with the pollen of the white moonflower; the procedure, employing the stigmal fluid, as described, was varied in that the pollen of the Bansai flowers was not removed. Several flowers, thus at once self-pollenated and reinforced with the pollen of the moonflower, produced seed.

In 1913 these two lots of seed were planted under like conditions; but from germination to maturity, the plants that were twice crossed with the moonflower were the most vigorous in growth and their flowers were more nearly true to type. For this reason, these plants that had been reinforced by inbreeding with the moonflower were selected to carry on the strain and marked Bansai No. 2.

The diagram attached hereto shows graphically the several steps followed in the seasons of 1911, '12, '13, and '14, in originating and in fixing true to type the hybrid morning glory Bansai.

The self-pollenated seed of Bansai, No. 1, produced eight plants in the second generation (1913), that were carefully watched during growth. None of these seedlings appeared to conform to Mendel's law, in resembling the male parent, more than did the original hybrid Bansai, No. 1, the female parent continuing dominant. There was, however, a noticeable decrease in the vigor of growth, compared with Bansai, No. 1, notwithstanding that the soil was rich and growth stimulated by watering with liquid fertilizers. The flowers were also somewhat smaller in size, and a tendency was observed to eliminate the white border.

About this time, the results of other experiments with these flowers indicated that this reinforcement of a hybrid, by inbreeding with its male parent, might be improved upon, by first depollenating the hybrid flower and treating the stigma with the developing fluid of the moonflower, as described, then applying the pollen of a number of flowers of the same hybrid, and finally rubbing in the pollen of the hybrid, using to do this both the anthers and stigma of two, or often three, moonflowers, thus in one operation fertilizing the hybrid flower with the pollen of flowers from the same plant, or preferably, with the pollen of selected flowers from another plant of the same hybrid, and blending therewith not only the vitalizing fluid of the stigma of the moonflower, but the pollen of the moonflower as well.

This method of dual fertilization was employed in the season of 1913 in the endeavor to fix Bansai No. 2 true to type, with the result that fully 50 per cent of the flowers so treated produced seed.

Diagram of the multiple hybridizing of a Japanese morning glory with the pollen of the white moonflower in producing the original hybrid and in the successive repollenations whereby the hybrid flower is made to reproduce itself true from seed, and has imparted to it an increased vigor of growth.

SEASON OF 1911.

Male Parent.
White Moonflower

Female Parent.
Red Japanese Morning Glory.

Depollenated and the pollen of the moonflower applied, by employing the reflexed flower as a brush.

It is supposed that in this instance some of the stigmal fluid of the moonflower was transferred in the process of pollenation to the stigma of the morning glory.

SEASON OF 1912.

Original Hybrid.
Bansai, No. 1
First Generation

Pollen not removed Stigma treated with stigmal fluid Finally repollenated with pollen of the moonflower.

SEASON OF 1913.

Bansai, No. 2.
Second, First Generation.

Depollenated. Stigma treated with stigmal fluid. Pollenated with the *pollen from* other plants of Bansai, No. 2. Finally repollenated with pollen of the moonflower.

SEASON OF 1914.

Bansai, No. 3.
Third, First Generation.

These seed, planted in 1914, produced Bansai, No. 3, the result of twice inbreeding the original hybrid with itself and with its male parent—in fact, Bansai No. 3 may be looked upon as *the third, first generation, of the original hybrid.* That no true second generation, or second year's growth, took place, counting from the year that the hybridization was performed, is of interest in its possible relation to the operation of Mendel's law.

The successive pollenations of the original hybrid with the moonflower caused a notable increase in vigor of growth, the leaves becoming broader and the white border of the flowers more prominent—in fact, the cumulative effect was to accentuate those qualities that appear to have been derived from the moonflower.

In Bansai, as thus developed and fixed, the female parent is dominant; it has inherited from the moonflower vigor of growth and increased substance in the flowers—the flowers are also marked by a white border; in all else, Bansai seems to inherit from the morning glory. Owing to the greater substance of the flowers and the marked permanence of the color, the flowers keep well; in this respect Bansai is superior to either parent. If picked early in the morning, the flowers may be kept in an ice-chest (at a temperature of about 55 deg. Fahr.) for 24 hours. On cloudy days, the flowers of Bansai remain on the vines without closing until

after sunset. The buds are long and large, and the flowers as they naturally open measure 3 to 4¼ inches across. The largest flowers I have raised measured 4⅝ inches across, without touching the flower in any way to enlarge it.

Bansai may truly be termed the first of a new type of morning glory. It is strong and vigorous in growth, the vines attaining with five months' growth from seed a height of 25 to 35 feet. The leaves are 5 to 8 inches long, shaped like an aeroplane, often with two pairs of wings in the same plane, situate near the axil of the leaf. The flowers are borne profusely, and have a brilliant carmine center with a margin of pure white one fourth of an inch broad. The color appears to be due to a dye filling the cells of the flowers; it is extracted by macerating the flowers in alcohol. The solution is of a clear carmine color, and reacts with acids and alkalies like litmus—changing to blue with alkalies and red with acids.

The method here set forth was tested in the season of 1913, with other varieties of the Japanese morning glory. In 1914 the seed of these hybridizations was planted, producing a number of new flowers of the Bansai type. It was noted that various shades of lavender, rose, blue, and purple, yielded when hybridized with the white moonflower new varieties, having the center of the color of the female parent, with a border of pure white, in this resembling Bansai. It is suggested that these new hybrids, in which the female parent is so uniformly dominant, constitute a new type, distinguished from normal hybrids in that the male parent has exerted only an influence upon the resultant hybrids. Should this view be confirmed by further study, they might be designated as *influence hybrids*. Other experiments, in which the morning glory was subjected to dual pollenation, the pollen of a different variety of morning glory being mingled with the pollen and stigmal fluid of the moonflower, resulted in many new and surprising hybrids; some with new colors, widely variant from the flowers from which they had been derived. Some of these new hybrids will be preserved and further cultivated to observe the results in future generations.

In conclusion: hybrids of the Japanese morning glory with the white moonflower seem not to be subject to the operation of Mendel's law or are only subject to it in a limited way; this may be owing to:

1. That for some reason, the white moonflower is immune from the influence causing the seedlings of hybrid plants to vary in the second year. In this connection it is worthy of note, that crosses of the Japanese and American morning glory, arising from pollenation by insects, follow Mendel's law.

2. That this exemption is due to some quality or property of the fluid excreted by the stigma of the moonflower.

Owing to the fact that it has not been found possible to hybridize the morning glory without employing the stigma fluid we cannot, with the information at hand, differentiate 1 and 2 so as to determine whether the exemption may be due to one or to the other, or to both combined. The cause of this apparent immunity remains to be determined by experiment.

In the successive repollenations of the original hybrid Bansai, No. 1, no true second generation has occurred; but only a series of progressive first generations; arbitrarily enforced, my working theory, in carrying out these experiments, having been that the type might be fixed and at the same time the vigor of growth increased, by judicious inbreeding as described.

The action of the excretion of the stigma of the moonflower in developing the growth of the pollen should be studied under the microscope. It may be found on further investigation that this stigmal fluid is generic in its action, and that it will also develop the pollen of other genera of plants, so that its possible employment generally in experiments in hybridizing is suggested. Also this work upon the Convolvulaceæ may lead to the search for similar stigma fluids in other monopetalous plants, particularly where hybrids do not occur in the ordinary course of nature.

The X-Ray Spectrometer*

A New Instrument for the Study of the Properties of Crystals

It is now well known that a homogeneous pencil of X-rays is capable of reflection by a crystal provided that the rays are directed upon the crystal at the proper angle.[1] If λ is the wave-length of the X-rays, d the spacing of the crystal planes, and θ the angle which the rays make with the planes, these quantities are connected by the relation $n\lambda = 2d\sin\theta$ [2], where n is an integer.

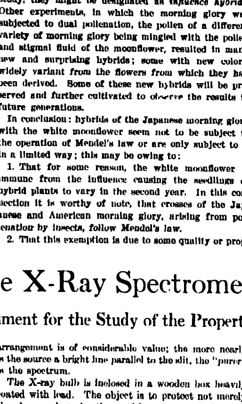
The object of the spectrometer is to determine the value of θ in any given case—that is to say, for a definite set of X-rays and a definite set of crystal planes. The results may be classified as follows: If we use different crystals or different faces of the same crystal, but keep the rays the same, we can compare the spacings of the various sets of planes. In this way we arrive at a knowledge of the relative positions of the atoms in the crystal that is to say, we determine its structure.

If we use the same crystal always, but examine the angle of reflection of different homogeneous X-rays, whether from the same or from different sources, we have the means of comparing the wave-lengths of those rays. We can, in fact, analyze X-radiation in exactly the same way as an ordinary spectrometer analyzes light.

The new instrument resembles the ordinary spectrometer in its general construction. To the collimator corresponds a set of narrow slits limiting a pencil of X-rays, which is directed so as to pass through the axis of the instrument. A crystal takes the place of the diffraction grating, and is mounted on a small revolving table. The crystal face or set of planes which is acting as reflector is made to contain the direction of the axis of the instrument, and the crystal is turned round the axis until the face makes the proper angle with the incident pencil. The reflected ray then enters a cylindrical ionization chamber filled with gas which it ionizes. The chamber takes the place of the ordinary telescope, and the measurement of the ionization current by an electroscope corresponds to observation by eye or by the photographic plate.

In the drawing,[3] which shows the arrangement of the apparatus in plan, Q is the antikathode of the X-ray bulb. The construction of the bulb is a little unusual in that the antikathode is placed perpendicularly to the kathode ray stream; the bulb can therefore be conveniently arranged so that the X-rays leave the antikathode at a grazing angle. The finer the angle which the rays make with the antikathode, the more nearly does the source become, effectively, a "bright" line; and the narrower the line the brighter it becomes, because the "whole illumination" given out in any direction by the spot on the antikathode is independent of the direction. The law followed is not that of the illumination by a surface of uniform luminosity, but rather that of the illumination due to a number of separate sources lying in one plane, each radiating uniformly in all directions. It corresponds to the case described by Rutherford, in which α rays are radiated from a uniform thin sheet of radio-active matter spread upon a plane surface (*Phil. Mag.*, August, 1906). The arrangement is of considerable value; the more nearly is the source a bright line parallel to the slit, the "purer" is the spectrum.

The X-ray bulb is inclosed in a wooden box heavily coated with lead. The object is to protect not merely the observer but also the sensitive apparatus. The slit through which the rays pass is only a few millimeters



long and very narrow, sometimes no more than a tenth of a millimeter wide. Only a small fraction of the pencil that emerges is reflected in the best circumstances, so that it is necessary to screen off all stray radiation with great care; it must be small in comparison with the radiation which is to be measured. Adjustable slits are placed at A where the rays leave the box, and again at B, the second slit being also capable of a movement which brings it close up to the crystal, as at B'. The crystal is shown at C, and a third slit, D, is placed just in front of the ionization chamber.

The ionization chamber is a cylindrical brass chamber 15 centimeters long, and is filled with some heavy gas, so that the ionization current may be as large as possible. Sulphur dioxide is convenient in many cases, but methyl bromide is much better for rays which can excite the bromine X-rays. Such rays are, for example, given off by antikathodes of silver, rhodium, or palladium, the latter two of which have been much used in the determination of crystal structure, because they give off intense homogeneous rays and also stand up well against the bombardment by the kathode stream. The chamber is insulated and maintained at a high potential, which drives any ionization on to an internal electrode. The latter is connected by a fine wire to the gold leaf electroscope (Wilson pattern) within the shield. The connection with the electroscope terminal is made at a point lying on the axis of the spectroscope, so that the ionization chamber and the connecting wire may revolve together about the spectrometer axis without straining the connection. The shielding is made solid and strong; it is necessary that the electrostatic screening should be perfect, and the electroscope must be protected from drafts which may cause changes in temperature.

The gold leaf is illuminated by reflection from a mirror, and viewed through a microscope. A strong X-ray reflection will cause the leaf to move twenty or thirty scale divisions in a second.

The angular positions of the crystal and the ionization chamber are read from the vernier shown. Observations can easily be made to half a minute of arc, and much finer work could certainly be done, if it were required. The actual angle of reflection can be measured with an accuracy higher than can be reached in our knowledge of certain other data used in some of the calculations; for example, the actual weights of the atoms.

Crystals are often very imperfect in construction, consisting rather of a conglomerate of smaller crystals in more or less imperfect alignment. It is interesting to observe that the spectrometer may be used in ways which almost completely overcome the evil effects of the imperfections. In the case of a very perfect crystal like the diamond, the slit at A is not used, but B is set very fine; D is wide open. The crystal is slowly turned by a tangential screw attached to the revolving table, and there is no reflection at all outside very narrow limits. The angle of maximum intensity of reflection can easily be determined to a few seconds of arc. But a crystal of rocksalt cannot be treated in this way. It is best to set A and D fairly fine and not to use B at all. On account of certain most fortunate geometrical considerations, a homogeneous pencil of some divergence issuing from A and reflected at various points on the crystal face is brought to a line focus at D, provided that A and D are at equal distances from the crystal (Proc. Roy. Soc., lxxxviii., p. 433). A perfect crystal would reflect such a pencil only along a certain vertical line on the crystal face; but a poor crystal, like rocksalt, at a number of separate points on the face Even crystals which are scarcely recognizable as such may be treated by this method

The higher order of spectra, that is to say, reflections at angles for which n has a large value, three, four, or five, naturally give more accurate values than lower orders, though the intensity diminishes rapidly as n increases. The "resolving power" increases even faster than n, since $d\theta/d\lambda$ is easily soon to be equal to $\tan\theta/\lambda$, which becomes very large as θ approaches the value $\pi/2$. For example, a certain pair of lines emitted by a platinum antikathode are separated by thirty minutes of arc in the first order spectrum reflected by the cleavage face of the diamond, but in the third order spectrum they are two and a half degrees apart.

With a little practice it is quite easy to pick up the reflected X-rays. While the search is being made the slits are opened wide; as soon as the reflection is observed the slits are made narrower, and accurate measurement is then possible. It is a comparatively simple matter to find the angles of reflection of rays of given quality in the various faces or sets of planes of a crystal. The greater difficulty arises in the geometrical interpretation of the results.

* Reproduced from *Nature*.

[1] A summary of the principles on which this experiment is based, and of the progress of its development may be found in *Nature* of July 9th, 1914, p. 404.

The Planet Jupiter*

Possible Explanations of Some of Its Phenomena

By Rev. Theodore E. R. Phillips, M.A., F.R.A.S.

Though lacking in those special features which in the popular view invest Mars with such an atmosphere of romance Jupiter nevertheless claims in an equal degree the close attention of telescopic observers. Indeed to the amateur whose optical resources are usually of a modest nature Jupiter affords a far more profitable field for work than Mars whose small disk only now and again presents developments on a sufficiently large scale to be well within the grasp of small apertures. Such a development on Mars has occurred in recent years in the Nepenthes I. Moeris, and Thoth region but broadly speaking it may be said that, even in large instruments, the approximately stable features of the smaller and more condensed planet cannot, in the nature of things present constant and unexpected changes such as demand the watchful attention and assiduous work of the observer of Jupiter.

As regards physical condition, it has long been recognized that Jupiter has many points of analogy with the sun. Its density is the same and it is generally inferred that like the sun it is in a heated and expanded condition and that if not still partially gaseous it is at any rate in a viscous and semi-liquid state. Many features too of superficial resemblance have been pointed out by various investigators. To refer to two of the most striking and obvious instances we may mention (1) The analogy between the spot zones on the sun and the belts of Jupiter and (2) the equatorial acceleration of both bodies.

As regards the first of these it has been suggested by Lau (*Astron. Nachrichten*, Band 195, No. 4673) that the reason Jupiter has belts instead of zones of spots is to be found in its rapid rotation. The material forced upward from the lower strata of the planet bringing with it a smaller linear velocity than that of the surface, streams eastward and assumes the appearance of elongated streaks. If the centers of eruption are sufficiently numerous belts are formed and it is suggested that were the sun's rotation much more rapid than it is the solar surface at spot maximum would also present dark streaks or belts.

In accordance with this theory of belt formation it will be remembered that the great revival of Jupiter's north equatorial belt in 1912-1913 began with the outbreak of a few isolated dark spots which quickly spread out round the planet.

As regards the second of the analogies above mentioned it will be recalled that the rotation of the sun can be fairly represented by a simple empirical formula the velocity being related to the latitude and diminishing from the equator toward the poles. Now Cassini, in 1690 found that a spot on the equator of Jupiter required about five minutes or so less for a rotation than an object in the southern hemisphere and subsequent observations have established the existence of a rapid equatorial current as a permanent feature of the visible surface of the planet. It is true that the cases of Jupiter and the sun are not quite the same, on the former there is no general increase in the rotation period with increasing latitude but a sudden and abrupt change in the velocity in both hemispheres at about latitude 7 degrees. The equatorial current of Jupiter is therefore like a mighty river sharply bounded by two banks which are usually indicated by the two great equatorial belts.[1] Beyond these the arrangement of the currents is unsymmetrical and dissimilar in the two hemispheres but notwithstanding these differences the analogy between the equatorial accelerations of the sun and Jupiter is very striking and it is hardly possible to doubt that the cause in each case is the same.

It is not intended in this article to discuss in any detail the physics of Jupiter but the analogy to which attention has been drawn between the planet and the sun, suggests certain possible explanations of some of the planet's phenomena.

(*a*) It has been found that certain sunspots appear to be vortices, and exhibit a whirling motion. It is suggested that many of the Jovian spots are of the same nature and are the results of disturbances whose origins lie at some depth below the superficial layers. Kritzinger (see *B. A. A. Journal*, volume xxiv No. 9) thinks it probable that in accordance with Emden's theory of the sunspot zones a number of discontinuous surfaces are developed within the planet, and that the edges of these different surfaces at the boundary of the disk produce the belts. The effect of two terrestrial atmospheric layers of different density with one gliding over the other in producing clouds of the cirro-cumulus type is well known and it is hinted that the Jovian spots have an analogous formation. Lau also (*Astron. Nachrichten* Band 195 No. 4673) considers that vortices are formed along the line of contact between the great equatorial current and the slower moving material north and south.

It is now very generally held that the Great Red Spot is a vortex. That it is not a solid feature of the planet is proved by its extensive wanderings but at least it is sub-permanent and has indicated a center of disturbance which has existed certainly for over eighty years as Denning and Kritzinger have independently shown, and probably for over two hundred and fifty years. The idea that the Red Spot is a vortex is well supported by the behavior of the dark material forming the South Tropical Disturbance or Schleier which has been so prominent a feature of the disk during the last thirteen years. Six times has the Disturbance which is situated in the same latitude as the Red Spot overtaken the latter and its behavior at such times though still in some respects mysterious is nevertheless instructive. Now it has been observed that as the *p* end of the Disturbance approaches the *f* shoulder of the hollow it becomes accelerated but that after its appearance west of the *p* shoulder it is retarded. The same thing is true of the *f* end. This is strongly suggestive that the Red Spot is a center of attraction, a vortex which draws into itself the surrounding material. It is, however not certain at what level the Disturbance moves. Lau considers that it passes under the white material overlying the Red Spot, and certainly little or no trace of it is seen during its passage across the bay. On the other hand, the outline of the Spot itself has sometimes been faintly discerned during conjunction, which suggests that the dark matter is mostly whirled round the periphery of the vortex and passes out on the *p* side. It has been observed that the time occupied in passing from the *f* to the *p* shoulder by the ends of the Disturbance is very decidedly shorter than the time usually required to move over the same distance elsewhere. The vortex theory also explains the formation of the bay or hollow in which the Red Spot lies since the drawing in of matter toward the center at the lower levels must be accompanied by an outward flow at a greater altitude. This latter may very well drive back the material of the south equatorial belt, and consequently give rise to the formation of the well-known bay at its south edge.

(*b*) The equatorial acceleration of Jupiter, like that of the sun, presents an interesting problem. Lau, in his

The planet Jupiter as seen in an inverting telescope.

* From *Knowledge*.

[1] The southern line of demarcation is usually between the two components of the south equatorial belt. In the northern hemisphere it is commonly at the north edge of the north equatorial belt, though when the belt is broad and double it is often [illegible] between the two components.

article above referred to speaks of it as a survival from an earlier condition of things, and apparently considers that it has its origin in the falling in of particles possessing a greater angular velocity than the planet itself. Whether the combined momentum of such particles would be sufficient now to produce an appreciable effect may be questioned, but if the masses of the planets and the sun have been in the past much increased by the accretion of meteoric dust particles revolving in direct orbits, the tendency would certainly have been to produce an accelerated superficial equatorial motion. A simple calculation shows that particles revolving close to the sun's surface would perform a revolution in roughly three hours, whereas the sun itself requires for a rotation at least twenty five days. For particles one hundred miles above the present surface of Jupiter and spots on the Jovian equator the corresponding times are 2 hours 57 minutes and 9 hours 50 minutes respectively. The same kind of thing is true of Saturn, and it seems quite possible that we have here at any rate one factor in the production of the equatorial acceleration exhibited by the larger bodies of the solar system.

A point which has attracted the close attention of observers of Jupiter is the variation in the velocity of different parts of the disk. Separate and distinct currents in the surface material of the planet whose latitudinal limits show only small changes have for several years been recognised, but their rates of motion are found to be variable. The drift of spots differs slightly from year to year, and there is reason to suppose that in some instances the variations in velocity are of a periodic nature, with minor fluctuations superposed on longer waves of considerable amplitude. Something of this kind seems probable in the cases of the Red Spot* and the great equatorial current. The motion of the former has been thoroughly discussed by Denning and by Kritzinger independently, and a period of roughly fifty years has been suggested. Fig. 7 shows the changes in the position of the Red Spot during the last twenty years. It will be seen that since 1901 the longitude has diminished by well over two hundred degrees. The rotation period attained a maximum value of 9 hours 55 minutes 42 seconds ± in 1899, but in the year 1913-1914 (from opposition to opposition) this had become reduced to 9 hours 55 minutes 35 seconds ±.

Fig. 8 shows the changes in the rotation period of the great equatorial current since 1879. The diagram is based on weighted values derived from the results of various observers (cf. papers by A. S. Williams, M.N., volume lxiii, page 14, volume lx, page 405, volume lxxi, page 145; W. F. Denning, M.N., volume lxiii, page 531; Major P. B. Molesworth, M.N., volume lxv, page 691, and so on; B.A.A. Jupiter Section Memoirs, and so on) and shows that the rotation period in 1913 was practically the same as it had been thirty years earlier. The curve exhibits a slight secondary minimum about 1900, which gives it some resemblance to the light curves of variable stars of the β Lyrae type, but observations extending over a much longer period are needed to show whether or not the changes are definitely periodic.

Some reference to the present appearance of the planet may be of interest. A comparison of the drawings of 1913 (see Figs. 1 and 2) with those of the current apparition shows that considerable changes have been in progress and illustrates those characteristics of the surface markings which render Jupiter so attractive an object for telescopic scrutiny. It will be seen from Fig. 5 that the South Tropical Disturbance is now clear of the Red Spot hollow, having just completed its sixth conjunction with that object, and that the Red Spot itself has once more emerged as a well-defined ellipse. To the writer, however, it shows no trace of red, but is neutral gray, presenting a striking contrast to the warm tone of the south equatorial belt. The longitude (ω_2) of the Red Spot at the end of August was about 202 degrees. The South Tropical Disturbance now extends over 110 degrees ± in longitude, the positions (ω_2) determined at Ashtead at the close of August being: Preceding end, 62 degrees +; following end, 173 degrees ±.

It will be seen that marked changes have occurred in the north equatorial, north tropical and north temperate regions of the planet. The brilliant egg-shaped markings which in 1913 formed a belt round the north part of the equatorial zone have become degraded into smaller and less regular white areas, while the dark protuberances are also very unequal in size, shape and distance apart. Observations of thirteen north equatorial markings down to the end of August give a mean rotation period of 9 hours 50 minutes 17.4 seconds, which is a slight increase on the value of last year.

Among recent developments must be mentioned the formation of dark spots on the north component of the north equatorial belt, with white intermediate areas (some of them very bright) on the region between the two components of the belt. Still more interesting is the form assumed by some of the dark markings. They are distinctly arched to the south and inclose small brilliant white spots, the appearance being suggestive of bridges or sometimes links of a chain. At least seven objects are of this character, and an idea of their strange form may be gained from Figs. 4 and 5. Observations of seventeen objects in this region show the rotation period down to the end of August to have been 9 hours 55 minutes 30.6 seconds.

Another striking difference between the appearance of the planet in 1913 and 1914 is furnished by the south equatorial belt. Almost uniformly dark in the former year, it has recently consisted of two widely separated bands with a pale orange region between them.

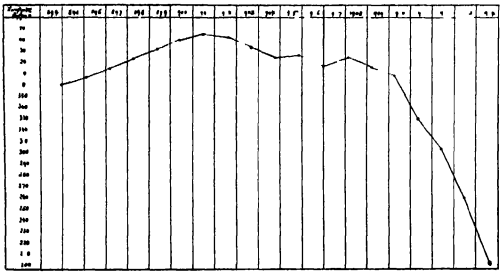

Fig. 7.—Position of red spot at opposition 1894 to 1914.

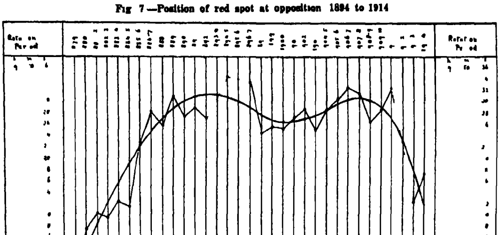

Fig. 8.—Rotation period of equatorial current 1879 to 1914. The value for 1914 is based on observations from May to August only.

*Some of the irregularities in the motion of the Red Spot have been associated with its conjunctions with the South Tropical Disturbance. During conjunction the motion becomes [illegible].

The Physiology of Worry*

By Erle D. Forrest, M.D.

With the possible exception of those in the period of happy childhood, everyone is at times a victim of worry. In fact, the average individual thinks of and accepts worry much as he thinks of and accepts disagreeable weather conditions—as one of the bitter things of life which must be taken with the sweet. In other words, he regards it as a fact, but does not attempt to analyze it. The wisest thinkers of all times have recognized the condition, and many well known writers have expressed their views of its psychology. What has not been sufficiently recognized, however, until very recently, is the importance of worry, not merely in itself as implying the absence of happiness, but as the cause of ills far greater than itself, the cause predisposing to secondary manifestations which would otherwise have been escaped altogether. Having fully comprehended this fact, the next logical step in scientific progression is to determine the exact mechanism by which these disturbances are brought about. Through the conjoined efforts of psychologists and physiologists we are just beginning to reach the true physical basis of this important subject.

The keynote of worry is beyond doubt a disturbance of the mind. It may be defined as the restless consciousness of all encumbrances which we accept under protest. To elaborate this definition, it is the mind's unrest about anything which concerns us, whether it relates to our future, our dear ones, a cause we have espoused, our happiness, our salvation, our means of support, our position in life, our health, our fate or our success in general. It does not consist solely in our interest in all these things; it is rather a disquietude arising from a feeling of helplessness before the various chances and claims of life. The popular opinion seems to be that the mental condition is one of depression, possibly because the physical manifestations are chiefly depressive in nature. The fact cannot be too strongly emphasized, however, that the primary mental condition is one of overactivity, and moreover, overactivity along lines of fixed ideas.

Without taking up individually the phases of worry brought about by the various specific causes, the physical manifestations of worry in general may be said to be—depression of respiration, sighing, disturbances in rate and force of heart beat, vasomotor changes, disturbances in secretion, pallor, cold extremities, relaxation and decreased motility of the alimentary tract, dilatation of the pupil, loss of weight, insomnia and general physical exhaustion. These disturbances may vary in their prominence and may appear as groups of symptoms characterizing well known diseases. Thus worry is sometimes an important agent in the production of diabetes, gout, exophthalmic goiter and chronic heart disease.

Inasmuch as worry is primarily a disease of the mind, and since every portion of the body is intimately connected with every other part by a net-work of nervous tissue of great complexity, we naturally seek for the causes of those manifestations first of all in the nervous system.

In every individual at a given time there is a limited amount of potential energy stored up in the cells of the brain. This function seems to rest in the chromatin granules of the nerve cells, and it has been shown repeatedly that a liberation of nervous energy, whether in response to a psychic or sensory stimulus, results in a physiological degeneration of the chromatin granules and consequently of the cells themselves. Obviously a prolonged discharge of nervous energy diminishes by so much the amount left in the brain cells. Furthermore, stimuli of sufficient number, intensity or duration may cause exhaustion and death.

* From the Medical Record.

Exactly this phenomenon occurs in the state of worry, except that the degree of fatigue rarely reaches the fatal extreme. Through mental overactivity, and the corresponding chromatolysis in cells concerned in mental processes, discharges of nervous energy to all parts of the body take place through the cerebrospinal axis and the sympathetic system. Whether the action of a given structure is augmented or inhibited, of course, depends upon its inervation. One of the most constant effects of such long-continued discharges, however, is the production of a certain amount of tonic contraction of most of the voluntary muscles, which, if at all noticeable to the individual, he describes as a slight increase of body tension.

A physiological degeneration of nerve cells is normally offset by a slow regeneration, occurring during the periods of physical and mental repose. In worry, because of the fact that the catabolic process is at first more rapid than the anabolic, gradually diminishing as the lower limit is approached, and because continued mental activity gives rise to insomnia, a period soon arrives when the expenditure of vital force in the shape of obvious work done has reached a point where the regenerative process, slow as it is, is just about able to offset the breaking down. The phenomena expressing the depletion of the vital force are termed "physical exhaustion" This is to be distinguished from "shock," wherein the stimuli lead to no obvious work done, and the expenditure of energy is extremely rapid.

The sympathetic system, probably because of its intimate relation to vegetative functions, seems to be susceptible to a much slighter degree of stimulation than are the nerves of the cerebrospinal axis When, in the course of events, therefore, the latter nerves are no longer able to respond adequately to the stimuli arising from the mental activity, the sympathetic is apparently capable of carrying on functions even greater than those which it is normally called upon to serve.

Bearing these facts in mind, we see a possible explanation of some of the various physical phenomena. For instance, stimulation of the sympathetic, with a decreased activity of the motor oculi nerve, causes dilatation of the pupil Depression of the vagus, phrenic, and intercostal nerves decreases the breath rate. The sigh, so often observed in worried individuals, is simply a very deep inspiration which occasionally takes place to compensate for what would otherwise be insufficient oxygenation of the blood. Through depression of the vagus and the simultaneous stimulation of the sympathetic, the heart action frequently becomes rapid and weak. The vasomotor changes are chiefly constriction of the peripheral vessels, due to stimulation of the sympathetic nerves. In this connection the reciprocal action of the veins of the omentum is brought into play, these vessels often becoming enormously distended with blood Constriction of peripheral vessels, combined with enfeeblement of the circulation, accounts for the palor and cold extremities so often seen. The secretions are often decreased in amount through narrowing of the vessels supplying the glandular tissues. The extremely dry mouth and lips which probably everyone has observed when he has been worried is a familiar example of this. The stimulation of the sympathetic may, on the other hand, be so severe as to bring about increased secretion in spite of the diminished blood supply, as is evidenced by the so-called "cold sweat" Inhibition of motility of the stomach and intestines appears to be brought about by stimulation of the splanchnic nerves, again a part of the sympathetic system.

In addition to the nervous system as a means of coordinating the various parts of the body there is a method which makes use of chemical processes. In some of the lower organisms this latter method is the only means of unification and is developed to a relatively high degree. The difference between the two methods is essentially one of time, the nervous system being obviously the more rapid by far. These chemical substances have been given the names "hormones" and "colyones," according to whether their functions are those of augmentation or inhibition. They are all included under the general heading of "internal secretions"

Internal secretions are substances produced by gland cells from raw materials furnished by the blood, which are afterward passed back to the blood or lymph stream, to assist in regulating the general nutrition of the economy or to serve some more specific purpose of equal importance to the organism. They differ from the better known or external secretions in that in all typical cases the latter are poured out upon epithelial surfaces which communicate with the exterior, while the internal secretions are discharged upon the closed endothelial surfaces of the blood and lymph vessels. With their development in any organism, a susceptibility to their action must arise in certain of its structures. In the broadest sense, internal secretions must be looked upon as something common to all active tissues, but the best known and probably the most important ones are produced in the liver, pancreas, thyroid, adrenals, pituitary body, and probably the ovary, testis, thymus, kidney, and spleen. From the standpoint of their importance in worry, those derived from the pancreas, pituitary body, thyroid, and adrenal glands seem to occupy first place according to the theories evolved as the result of the most recent investigations.

For experimental corroboration of our theories we are compelled to make use of animals, such as the dog and cat, because of the fact that chemicophysiological experiments such as these necessitate extensive and dangerous surgical procedures. Therein lies a great difficulty. Although the animals are readily obtainable we are never sure that a condition of worry analogous to that found in the human organism is simulated. These animals are, however, visibly susceptible to agencies producing fear, and by modifying the results obtained while they are in this state, in accordance with the intimate relation known to exist between fear and worry, many of the theories regarding the influence of the internal secretions may be substantiated.

The function of the internal secretion of the pancreas seems to be that of assisting in the combustion of glycogen, the product of starchy materials ingested as food, in the muscles. Muscular energy is derived from this oxidation, but in order for it to take place two ferments, one produced in the muscle itself, and the other the internal secretion of the pancreas, must be present in quantities of a certain definite proportion. If the balance is destroyed it cannot take place, and the sugar accumulating in the blood to more than the normal percentage appears in the urine.

Two theories as to the part which worry plays in diabetes deserve consideration. The first is to the effect that the pancreatic ferment is decreased, owing to constriction of the blood-vessels in the glandular tissues. The other is that by stimulation of the sympathetic nerves the secretion is increased. The latter theory seems to have the more supporters, but in either case diabetes results from an overturning of the balance between the muscle ferment and the product of the islands of Langerhans.

Worry also seems to increase the internal secretion of the pituitary body. Recent experiments show conclusively that an excess of pituitrin in the blood, without other complications, produces a marked rise of blood pressure and a slowing and strengthening of the heart beat. It appears to slow the heart by acting upon the peripheral endings of the vagus, the nerve whose function it is to bring about that phenomenon normally An interesting feature of its effect upon vasomotion is that while most of the peripheral vessels are constricted the arterioles of the kidneys are dilated, allowing an abundant supply of blood to those organs. At the same time, pituitrin exerts a direct stimulating effect upon the secreting cells of the uriniferous tubules. These three factors increased blood supply of the kidneys, increased blood pressure, and hyperactivity of the secreting cells —may well account for the marked diuresis so often observed in worried individuals.

Occasionally, after long-continued worry or extreme fright, the symptom complex—known as exophthalmic goiter—is observed. It probably does not affect an individual unless a previously enlarged or disturbed thyroid gland is present. However this may be, the disease is undoubtedly associated with a hypersecretion by this gland. Since it is supplied by the sympathetic it seems reasonable to infer that this oversecretion is brought about by the stimulation of its controlling nerves. An excess of this substance in the blood, in contrast to the effects of pituitrin, dilates peripheral arterioles, probably by a direct action on the muscle in the vessel walls, bringing about a visible flushing of the skin. It also appears to have an antagnostic effect upon the substances which influence the nutrition of the body, as is evidenced by the rapid loss in weight in this disease and the excretion of large quantities of nitrogen, carbon dioxide, and water in the urine That it has a definite action upon the nervous system is shown by the tremor usually present. The pulse is at the same time rapid and throbbing in character.

The effects of the internal secretions thus far considered must not be regarded as constant manifestations of this emotion. In fact, the cases are relatively rare in which diabetes and exophthalmic goiter do occur. Inasmuch as we have come to ascribe to all body tissues powers of secretion, is it not entirely reasonable to presume that secretory disturbances in one organ may be offset or held in check in a majority of cases by products of other structures? We know this to be an almost universal principle in animal function, exemplified by the opposed actions of the vagus and sympathetic in the control of the heart. Denied this liberty, we can only, at present, make use of the vague term "individual susceptibility" in explaining this seeming inconsistency.

There is an internal secretion, however, that of the adrenal glands, which appears to be always associated with the most constant effects of worry. Adrenalin, or epinephrin, as it is called, is an excellent example of the manner in which most of the internal secretions and the nervous system interact and supplement each other, for it has been shown that it does not act upon any organ or tissue which has no sympathetic or autonomic nerve supply. In fact, its point of attack appears to be the end arborisation of the nerve fiber where it joins the muscle or tissue. The presence of physiological quantities of adrenalin in the body seems to be a necessary condition for the normal functioning of the entire autonomic system.

The secretion of adrenalin is controlled by the sympathetic and is increased in worry. We cannot say that its presence in the blood in abnormal quantities is responsible altogether for the phenomena which are dependent upon the autonomic nerves, for we have seen how the increased stimulation of the sympathetic, by means of mental overactivity, can bring about these things. It does, however, magnify the action of the sympathetic and is capable of maintaining this action alone, for a considerable period of time after the sympathetic stimulation has been removed. The latter phenomenon is accounted for by the fact that there is an autogenous continuance of most of the internal secretions, including adrenalin. In other words, these substances, coming in contact with the tissues which originally produced them, tend to stimulate still further production After a time, however, even this mode of adrenalin derivation ceases, for the blood gradually gives up its epinephrin by aeration in the lungs.

After the foregoing discussion it can readily be seen that many features of worry have not been considered. This condition, together with its allied emotions, constitutes an enormous field for further scientific investigation. In view of the rapid improvement which modern laboratory technique is undergoing, and the increased interest with which experimentalists are viewing psychophysiological matters, there is a great probability that within the next few years many of the remaining doubtful points will be satisfactorily explained.

Storing Heat

According to a story in *Power* a state dinner was to be given in a castle in Germany in which there was no heating system, but as this mediæval condition could not be tolerated in modern times, for the dinner was a function of recent occurrence, the engineers were asked to heat the building for the occasion; but it was specified that no portion of the heating system was to be visible in the room. The result was accomplished by means of stored heat. For a number of days previous to the dinner, the floor of the dining room was covered with steam pipes and these pipes were kept hot by means of a temporary boiler. The day before the dinner all the pipes were removed and the stored heat in the walls maintained the room in a perfectly comfortable condition for a number of days, although the outside temperature was well below the freezing point.

Organic Matter in the Soil

In the annual report of the Bureau of Soils of the U. S. Agricultural Department is the following statement in regard to the importance of the organic matter contained in soils:

"Organic matter is essential to make a soil of what would otherwise be pulverised and more or less hydrolised rock, and while there are some soils that contain small quantities of organic matter capable of growing crops, on the whole the quantity of this material in average soils is considerable. The average organic content of soils amounts to approximately fifty tons per acre, and yet the nature of this material has been but little understood. It has been believed for many years that it consisted chiefly of some such body as humic acid, differing perhaps in different soils, but having the same general properties. One prominent service which these investigations have rendered agriculture has been to show the non-existence of humic acid and its hypothetical relatives and to show instead the existence of many compounds with many relationships.

"This line of research has been especially profitable during the year just past, and the number of compounds isolated and identified has been increased to more than forty. Some of these compounds contain only carbon and hydrogen; some carbon, hydrogen, and oxygen; some carbon, hydrogen, oxygen, and nitrogen; others contain phosphorus or sulphur. Isolation in a pure condition of these organic constituents of soils has made possible the correct interpretation of the changes that organic matter undergoes in soils. The compounds found are recognized as representing decomposition products of fats, carbohydrates, proteins, and other classes of natural compounds, and a great deal of light is shed thereby on the processes of humus formation and transformation in the soil. These researches into the nature and properties of soil organic matter have shown conclusively that the soil investigator must take into consideration the presence of organic compounds in the soil."

Peculiarities of Earthworms*

Compound Forms That Are Hard to Explain

By Prof. Dr. E. Korschelt

It is not so very unusual to find double or multiple forms among animals, such compound structures in particular not being especially exceptional among segmented worms. Some years ago Prof. Dr. E. Korschelt described in the "Zoological Year Book of 1904" earthworms of double and triple form, peculiarities of structure which had been gained mainly by experiment. He now writes an interesting article in the *Umschau* upon an earthworm with a double rear end, the origin of which is difficult to explain. This earthworm, one of the species *Helodrilus longus*, was found out of doors and was still in an immature state. In crawling the front had measured to the spot where the rear end forked 7.5 centimeters, the right branch of the rear end 4 3 centimeters, the left branch 4 centimeters (Fig 1).

Apart from the fact that the worm was somewhat clumsier in its movements than one of normal form, its way of moving varied but little from the ordinary. When placed upon loose soil it soon bored its way into the earth and quickly disappeared. When crawling the contractile waves passed simultaneously from the front end to both rear ends, which worked normally during the crawling. The transmission of irritation was as usual from the front end to the rear ends and *vice versa*, a point that was easily settled by touching the end of the head or of the tails. From this may be deduced the continuity of the main nervous system, as well as of the vascular system and of the intestinal canal. The arrangement of the rows of bristles and the way they fit into each other is best seen from Fig 2. At the forking there is some irregularity in the arrangement of the segments which overlap suitably to the dividing of the body (Figs. 1 and 2) In Fig 2 is shown by dots the respective positions and course of the rows of bristles from the ventral side upward.

It is not possible to determine from the condition and manner of action described whether this anomalous structure has existed from the beginning, that is, whether it is the result of the development of the embryo, or whether the double form has arisen from an injury If the worm had been injured when young so that a new rear end grew out from the wounded spot, or if the tail end had been completely lost and, on account of a suitable conformation of the surface of the wound, two rear ends grew out of this, there could follow under the circumstances, a far reaching rearrangement of the segments and it would hardly be possible to determine the difference of this form from a double structure arising from embryonic development This has been proved by a fairly large number of double-tailed worms produced by Dr. Korschelt by means of experiments. He says further:

"During some earlier exhaustive researches observations were made as to the length of an earthworm's life, which led to the surprising conclusion that these worms can live ten years and more The writer is now able to give more exact information as to the conditions of their life It is entirely accidental that these observed worms were ones upon which transplantations had been made. It was not intended at the time to determine the length of life but merely to watch the changes which might arise from the operation made upon the worms. For this purpose they were subjected to observations covering a long period of time In addition, the selection of the species of earthworm, *Lumbricidæ*, was also accidental and was brought about by the kind of operations made upon them, just as this, on the other hand, influenced the life of the respective worm. The life of the *Eisenia* (*Allolobophora*) *fœtida* was, for instance, a relatively brief one, being from 3¼ to 4½ years. This brevity of life can be accounted for in this way; either the unions of parts were such as not to have much vitality, or external circumstances affected the length of the respective experiment and shortened the period of observation. This latter explanation holds true for the single specimen of *Lumbricus terrestris* (*L. Herculeus*) which was kept for a considerable length of time and which lived to be 5¾ to 6 years old. Experiments were made on a larger scale with the *Helodrilus longus* (*Allolobophora*) [*Lumbricus*] *terrestris*, and somewhat by chance a large number of specimens of this species of earthworms was preserved for experiment, and for these worms the carrying out of the experiment permitted as a matter of course a longer lease of life for the united portions. The respective specimens lived for 6¼, 7¼, and 10¼ years."

It should be remembered in connection with the ages given that these were worms which were kept in confinement under rather limited conditions of space. The question could be raised whether these conditions are not more likely to produce a prolongation rather than a curtailment of life, as the imprisoned worms lived in comparative inaction and their forces were only exerted to a small degree. It is difficult or indeed hardly possible to answer this question with certainty so long as we know nothing positive on this point concerning worms that lead a natural life, especially as we do not know whether they pass through longer or shorter periods of inaction. In general, the earthworms are probably not much affected by unfavorable conditions of temperature and weather, as it is possible for them to go down to considerable depths in the ground. How far they really do this cannot be determined with certainty from the observations so far made It seems that earthworms go down

Fig. 1.—Rain worm with double rear end.

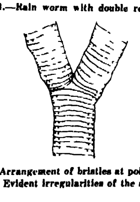

Fig. 2.—Arrangement of bristles at point of separation. Evident irregularities of the segments.

2 to 2.5 meters in the ground Their burrowing can be easily traced down to 2 meters, so that those which are long enough lived to do this seem to be well protected against the cold. On the other hand, frozen earthworms have been found in the ground at about a depth of 0.5 meter. The question here is whether such worms could not awaken to new life if the cold were not too severe and too long continued.

There have been repeated accounts of earthworms on and in ice and snow Experiments in freezing them have also been made which show that earthworms, and also other Oligochætæ, can bear relatively low temperatures without permanent injury. Dr. Korschelt made experiments with various Oligochætæ which were exposed for a considerable time in glasses of water to the almost complete freezing of the water. The experiments were up to 24 hours in length at a temperature of 5 deg. Cent, and lower, and the worms began to move again after the water gradually thawed out. They were absolutely vigorous and were observed for weeks further Taken altogether, earthworms seem to have less power of resistance, although in the experiments made on them they always bore temperatures down to 5 deg. Cent, for though they seemed to be frozen stiff they always revived to fresh life.

"It is safe to deduce from these experiments and observations which have been continued up to the present time," continues Dr. Korschelt in discussing his experiments, reports on which he has published in various scientific journals, "that the worms under natural conditions can bear a fairly low temperature, go through a certain condition of freezing and then wake up to a new life. Earthworms which are dug up in winter after a period of frost hardly move at all and seem frozen, but in the temperature of a room they soon become more animated and crawl about. It is most probable that the earthworm goes through a period of torpor something like hibernation at a considerable depth in the ground At any rate, just as such early observers as Morren, Hoffmeister, and Hensen stated, they are found in the enlarged ends of pipes, rolled up in a ball either singly or in nests."

According to observations made upon imprisoned earthworms by our author, they can also pass through periods of torpor of another kind, namely, periods which protect them from droughty conditions. When moisture is lacking for them they withdraw into the depths of the ground as far as possible, and they are found rolled up close together in an underground hollow which has fairly firm walls, smooth on the inner side and apparently held together by a secretion of the worm. If the torpidity lasts a good while, the worms lose decidedly in volume, become shorter and show retrogression, especially of the genital region. This may be explained by the loss of water and the insufficient amount of nourishment taken during this 'dry sleep" If this condition does not last too long and the worms become moist again, they then come out of the earth-capsule and under normal conditions resume their former mode of life.

"These observations show a certain agreement with those communicated by several other investigators but traced to other causes," says Dr. Korschelt. "Thus W. Harms remarks when making experiments in transplantation, that the earthworms lying in a round hollow would tie themselves up into a 'tight knot' after they had stopped taking nourishment while still moist and when sufficient nourishment was present The worms, consequently, had fallen into a kind of 'heat torpor,' in which if it lasted too long, certain retrogressions of their organisms would appear similar to those described above in 'dry sleep,' and this could lead to considerable reduction in size, as a shortening of the body. Somewhat different are the statements made by Vejdovsky, according to which his observations concerning the appearance of torpidity in earthworms both out of doors and in imprisonment were not to be traced to conditions of temperature and weather, but rather to exhaustion after continued sexual activity. That those earthworms which had burrowed down into round holes in the ground had also, as in the above mentioned cases, suffered a reduction of the genitalia as well as one of the bulk of the body seems very probable from Vejdovsky's statement As the holes in the ground have a fairly firm wall, Vejdovsky speaks directly of an 'encysting,' and compares it with the encysting of another Oligochætæ, the *Aelsoma*, which both he and Beddard had observed. This latter, a water worm, when unfavorable conditions appear secretes around itself a layered envelope in which it lies curled up. It thus passes through the unfavorable weather, and when conditions are once more suitable it comes out of the envelope. The author himself has had occasion to produce by suitable measures the encysting of this worm in a thickly populated Aeolsoma culture and thus to confirm the observations made by the two above-named investigators."

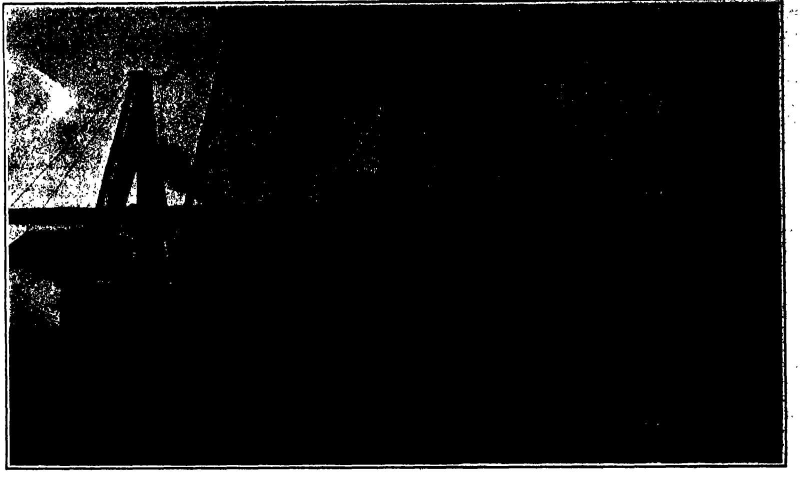
The exceedingly scanty number of observations concerning the torpidity and encysting of the Oligochætæ has just been increased by an observation made by Mrazek on the *Claparèdella*, another worm which lives in the water Those worms are accustomed to live at spots which are exposed to drying up. When there is danger of this dryness they creep under the fallen leaves in the deeper layers of mud, roll themselves up here and secrete around themselves a glutinous covering In Mrazek's opinion this action may also have another meaning, namely, that processes of separation in the organism of the worm may take place within this capsule.

The object of these communications was to compare the prevailing conditions among earthworms with those existing among the other Oligochætæ, and by the appearance of undoubted periods of torpidity among the latter to strengthen the conclusion reached concerning the former This does not settle the point how far these conditions of existence affect the question of the age attained by earthworms, but even if certain reductions have to be made in the figures of 6, 8 and 10 years obtained for the ages by direct observation, the figures that remain far exceed all expectations.

* Translated from *Umschau*.

A Russian Embargo on Woods

The Forest Service of the Department of Agriculture is authority for the statement that the Russian government has placed an embargo on all kinds of lumber, to prevent its exportation; walnut lumber, including Circassian walnut, much prized by American furniture makers, is specifically mentioned.



Showing cofferdams, molds, and reinforcing bars of the piers of the Pennsylvania viaduct.

Concrete Viaducts on the Pennsylvania Railroad

Replacing Insecure Wooden Trestles With a Substantial Road Bed

By Day Allen Willey

When the Pennsylvania Railroad Company built its line from Philadelphia to Washington the use of concrete for viaducts and bridges was unknown to the engineer. When the surveyors went over the proposed route between Havre de Grace, on the south of the Susquehanna, and Washington they found it necessary to make soundings of three inlets to the Chesapeake named the Bush, Gunpowder, and Back rivers, and it was found that the beds of these inlets consisted of liquid mud to a depth of over fifty feet. The plans for bridging these inlets provided for wooden trestles, the supports consisting of wooden piles driven into the mud formation which formed the bottom of the inlets and strengthened by a double row of braces fastened diagonally between each pair of piles.

The structure was so weak owing to the uncertainty of the foundation that parts of its frequently gave trouble, delaying train service until the defects could be remedied. The engineering department has always realized the necessity for permanent viaducts over the Bush and Gunpowder rivers having firm foundations, and it was decided to replace the frame structures with reinforced concrete viaducts.

The right of way was ample, but it was desired to put in the new bridges with as few new curves as possible, and these conditions were met by throwing the new bridge alignment on a slight angle with the old. The center line for the bridges was carefully laid out and measured on the ice in the winter, making careful corrections for temperatures, and using a standardized tape.

The old bridges were used as base lines and the new line was tied in at numerous points. At each bridge site a small concrete pier was erected on the shore for locating the center line, with three wooden blocks inserted for the tripod legs, and the point was located on this pier, and a foresight was carefully placed in the water. Thus, practically all the points were located using a foresight. Permanent backsights were established, but were only used when the foresight was obscured by smoke, hazy weather, etc.

The river mud was of the consistency of silt and was removed by pumping. The piling for the foundations was driven by steam hammers, attempting to reach the desired penetration with each pile. In some cases, however, it was impossible to obtain the penetration necessary, probably owing to the piles striking a conglomerate. Whenever it was impossible to obtain the desired penetration two extra rows of piles were driven for the pier, and the footings were spread. Wooden cofferdams were used, constructed of 6 by 10 sheet piling, which were driven with a small rapid action steam hammer. The pumps which excavated the mud were located on a small barge, and no difficulty was experienced in pumping the material 2,800 feet through 12-inch pipes. The piles were cut off so as not to extend more than 2 feet into the footing, provided the desired penetration was obtained. Where the first pile in the pier brought up above this point the remainder of the piles were sawed off accordingly, so little cutting off was necessary after driving.

To make a solid and firm bed for the concrete foundation a large wooden funnel was built, with an opening so small that the gravel would not run out fast enough to stir up the mud. This funnel was loaded with gravel and slowly moved around over the cofferdam. This process was continued until a layer one foot thick was placed, and then it was ready for the concrete.

A concrete plant was built on barges at each river. A large hopper divided into two parts was kept supplied with sand and stone by a clam shell bucket, unloading from barges alongside. The cement was stored on the main barge, and in the first plant built, at Bush River, the cement was carried to the mixer by laborers. In the other plant the cement was carried forward by an endless chain conveyer.

The concrete was raised in an elevator to the top of the tower and poured through the piping into the forms by gravity. The collapsible forms for the connecting arches were made of 3½ by 3½ by ¼ inch angles in five parts. The upper ones were bent to the radius of 4 feet 3 inches. Quarter-inch boiler plate was bolted to these angles, and the angles were bolted to the wooden pier lagging, and aided considerably in holding the pier forms in proper alignment.

The economy of steel truss supports is apparent, there being about 290 spans of the same length in the two structures. These trusses were set up on jacks and upright timbers with wedges between, resting on horizontal transverse timbers, which in turn were supported on the pedestals of the piers.

Jack screws were used to bring the trusses to the proper height, also to let down the trusses when striking. The trusses were lowered directly onto a barge, and towed to the next pier by a gasoline tugboat. The forms for one span were frequently collapsed, hauled to a new position, and jacked up into place in three hours.

Expansion joints were provided at every third pier. These were made by layers of cheap felt paper, making a thickness of one inch. The footing is 10 feet wide, 33 feet long and 6 feet thick.

The piers and footings are provided with steel reinforcing to take care of unequal strains or settlements. The footings have 1-inch square twisted steel bars as follows: 2 longitudinal bars 33 feet long, just outside the vertical pier bars; 10 transverse bars on about 3 feet centers, with an extra one between the two bars at the center of the piers.

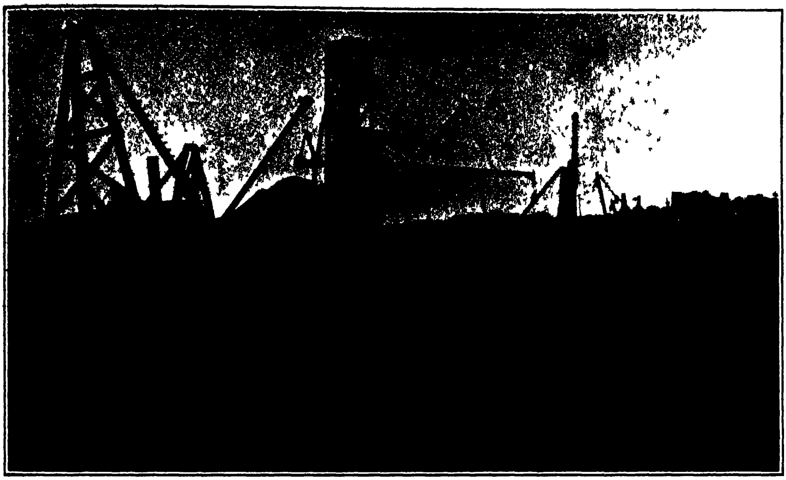
The tops of the floor slabs have a drainage slope from all directions to the 4-inch drain pipe placed at the center of the slab, so water can flow directly into the river.

An idea of the extent of this construction, which was let out in one contract, is given by the following quantities of material needed: Combined length of bridges, 7,714 feet; total number of piles, 13,777; number of yards excavated (wet) 97,000; yards of concrete masonry, 76,400; reinforcing steel rods, about 3,850 tons.

There are 186 duplicate regular piers, two abutment piers, two rest piers, and one center pier, all of reinforced concrete, with pile foundations. The footings, 6 feet deep, are made of concrete mixed nominally in the ratio of 1:2:4, and an additional 20 per cent of cement to compensate for wash due to the deposition of the concrete under water. Bottom dumping buckets were used in the cofferdams before the latter were pumped out.

Work was commenced on the viaducts March 15th, 1912, and the entire structure was completed September 15th, 1913. Considering the difficulties encountered in connection with the pier work, the construction was completed in a remarkably brief period, the average working force being only 400.

To test the strength of the viaducts a train of 60 loaded freight cars, each car weighing 60 tons and drawn by one of the most powerful locomotives in service, weighing over 100 tons, was hauled over the structure at a speed of 25 miles an hour without causing the slightest vibration.



Concrete mixing and distributing plant on one of the Pennsylvania viaducts

Actual Instances of Dual Personalities—II*

Cases in Real Life That Rival the Wildest Fiction

By Edward Tyson Reichert, M.D., Sc.D., Professor of Physiology in the University of Pennsylvania

Concluded from SCIENTIFIC AMERICAN SUPPLEMENT No. 2035, Page 3, January 2, 1915

THE history of Mary Reynolds was reported by Dr. S. Weir Mitchell to the College of Physicians of this city in 1888. The subject was a very impressionable girl. A nervous shock resulted in the development of multiple personalities which existed over a period of years, her normal personality, as in the cases of the fictitious Dorothy and the real Miss Beauchamp being restored by hypnosis.

Miss Reynolds's family moved from England to the wilds of western Pennsylvania during the early part of the eighteenth century. She is said to have possessed an excellent mental capacity and to have enjoyed fair opportunities to acquire knowledge. Besides the domestic arts and social attainments she had improved her mind by reading and conversation. Her memory was capacious and well stocked with ideas. She was sedate and reserved and tended to melancholy. When eighteen years of age she had hysterical fits and after one of these attacks was blind and deaf for six weeks. About three months later after having almost wholly recovered her normal health she fell into a profound sleep which lasted about twenty hours, upon awaking from which memory had completely fled and she was to all intents and purposes a being for the first time ushered into the world. Her parents, brothers, sisters, and friends were not recognized; the scenes to which she was accustomed—the house, hills, field, forest, vales and streams—were new. She began to learn, but always when in this new personality she looked upon those she had once known as strangers and enemies among whom she was by some remarkable and unaccountable means transplanted, though from where she had not the remotest idea. She learned to read and write, but her handwriting was not the same as that of her primary state.

Instead of being melancholy she was cheerful to extremity, buoyant and sociable. Formerly taciturn and retiring, she was now merry and jocose, extravagantly fond of company, and enamored of nature.

Six weeks after the appearance of her second personality she fell into a protracted sleep, from which she awoke in her primary state, recognizing the members of her family, remembering what she had planned as though but yesterday. She was absolutely without memory of the events of existence of her second personality and was greatly surprised at the change that occurred in nature over night.

Remaining in her primary state for a few weeks she again fell into a sleep from which she awoke in her secondary personality, now beginning life where she had left it weeks ago when she re-entered the life of her primary self, having now only the knowledge of her secondary state. Her vivacity, wit and humor were now so great as to make her company very much sought, but her love of playing tricks upon others often led to much trouble. Alternations in personality went on for fifteen or sixteen years, the secondary personality tending to remain for increasingly longer periods, when she assumed the second personality, continually existing in this state for the remaining twenty-five years of her life without the least knowledge of her other self beyond what had been told her.

Another case in some respects similar to that of Miss Reynolds and known as Félida X. was studied by Dr. Azam and has become world renowned. Félida came under Dr. Azam's observation when fifteen years of age. She had had many hysterical and other troubles which led to her becoming a timid, serious, grave and melancholy individual who was burdened with anxiety and pain. Appearing to faint away for a few moments she would awake, having an entirely different personality. Her pain, anxiety and other mental and physical infirmities had vanished and she was gay, vivacious and coquettish and morally perverted. She remembered the incidences of her normal life as did Sally of the life of Miss Beauchamp, but when in her primary state, like Miss Beauchamp and Miss Reynolds, she had no knowledge of her secondary state. These personalities alternated with great frequency but the primary state lasted for shorter and shorter periods and was ultimately crowded out as it were by the secondary state, as in the case of Miss Reynolds, which thereafter constituted her constant personality.

It is probable that in the cases of Miss Reynolds and Félida the personality which at first was recognized as the secondary personality was in reality the primary personality or normal state, and that the personality that was ultimately established was in reality not the secondary but the primary.

In these cases of dual personality the nature of the change in the individual's moral character may differ very widely. We have seen in the instance of Dr. Jekyll and Mr. Hyde a form of moral monstrosity that is manifested in an inherent maliciousness and a demoniacal pleasure in the infliction of torture on others—a form of immorality that arouses hate, fear and loathing. In the cases of Becky, Sally, Mary Reynolds and Félida there were forms of moral perversion that led to the annoyance of themselves or others or of such a kind as to engender sympathy. The most pathetic among these instances of marked moral alienation was that of a young woman, recently a patient in this city, who in her natural state was the personification of all that is attractive, lovely and sublime in young womanhood, and who at times upon awaking from a deep sleep would have an entirely different personality, with manifestations of moral monstrosity that vied in vileness with those of the denizens of the tenderloin.

In many cases the secondary personality appears but once, and sooner or later gives place to the normal. An interesting instance belonging to this category was reported by Dr. Osborne. The subject was a man of middle age, in admirable health, very fond of his family, and not known to have any eccentricities, morbid tendencies or bad habits. For years he had resided in a town near this city, and by strict application to his business, which was that of a tinsmith and plumber, had been successful and accumulated some means. One dull and gloomy Sunday in November he mysteriously disappeared. He had remained in the house mainly engaged in reading and playing with his younger children until 4 o'clock. Arising from a couch upon which he had been reclining and reading, he said that he was going out for a short walk and a little fresh air. Leisurely, quietly and apparently perfectly normal he stepped outside of the door to disappear as mysteriously as though the earth had swallowed him.

Two years later in a tin shop in one of the southern towns where a number of men were engaged at work, one of the men suddenly dropped his work and press

* A lecture delivered at the University of Pennsylvania, October 1914.

ing his hands to his head in a dazed way exclaimed "My God where am I? How did I come here? This is not my shop What does it mean? At first the men were disposed to laugh and jest at the man who for several months had been so reserved and sober and who had worked so quietly by their side but of whose history they knew nothing Seeing his changed expression his face wet with perspiration and his nervous twitchings and hearing his piteous appeals they became startled and called him by a name that was strange to him yet the one he had given them Trembling with suppressed emotion he made his way to the proprietor and with some difficulty made the proprietor understand his true condition and the story of his northern home family and prosperous business which as it seemed to him he had left but the afternoon before Under the assumed name he had been known and paid but the entire period from the time he left home until the present was a complete blank After ascertaining the whereabouts of his family he joined them and from last accounts was living the life of his normal self

A variable number of different personalities may develop in a given individual the person living as many different lives each being partly or wholly ignorant of the existence of the others Thus a man by the name of Monks a son of wealthy people who lived in London lived four different lives mingling in four different classes of society and having four different sets of friends As a conscientious clerk he was quiet retiring deferential cared little for the society of women did not smoke and was extremely exemplary in his habits As a professional bicycle rider he was loud voiced boastful swaggering profane a smoker and a drinker As a society man he was a fashion plate in his attire of graceful ease and extremely popular with the ladies four of whom in different parts of London he was engaged to marry As a burglar he was most skillful and daring and it was only after years that shrewd detectives ran him down and not knowing of his peculiar mental state had him committed to prison as a common criminal

A case of a man having six personalities was reported by Bourru and Burot In the first personality he was talkative violent arrogant rude disrespectful anti religious embarrassed in speech and with limited though precise memory In the second personality he was reserved gentle in speech orderly respectful without religious opinion and his speech was easy and pronunciation clear and he had little memory of the past In the third personality his state was very much like the second but his memory was limited entirely to the third state In the fourth personality he was timid sad well mannered and his intelligence was obtuse his memory confused and his language incorrect and childish In the fifth personality his mental state reverted to the period when he was fourteen years of age He had the timidity language and attitude of a child and was without memory of any of the incidents of his life subsequent to this time In the sixth personality he was a proper young man a soldier of the marine corps and his memory embraced his entire life excepting the period known as his fourth state

In a young girl as many as ten personalities were developed in twenty months and in one of them she reversed everything—to her white was black heat was cold etc and even her writing was reversed

Among all of these remarkable cases of dual personality none is on the whole so interesting and so instructive as that of the Rev Thomas C Hanna which was carefully studied by Drs Sidis and Goodhart ("Multiple Personality" 1905) and no summary however brief would be adequate without at least some reference to this extraordinary record The differences in the personal traits the complete loss of memory in the secondary state the gradual childlike acquisition of knowledge the childlike wonderment of what was seen and heard and the ultimate recognition of the existence of two personalities with their separate lives and their final blending form one of the most absorbing stories in psycho physiological literature

The Rev Mr Hanna was born in 1872 and had an exceptionally good family history and all the advantages of an excellent education and was a good scholar He entered the Manual Training School of this city and his high scholarship gained for him admission as a free student to the Architectural School of this university During his stay with us his sense of religious conviction became so awakened that he gave up his studies for those of theology and in order to prepare himself for the practical duties of the ministry he took up missionary work

He had an earnest ardent sympathetic and impulsive nature was well balanced and possessed a strong will combined with perfect self control We find him at twenty five years of age the pastor of a church at Plantsville Conn

At 7 o'clock one Thursday evening when attempting to alight from a carriage his foot caught in a lap robe and he fell head foremost, striking his head, and when picked up a few moments later life seemed almost extinct. In this state he remained for two hours, then began to move looked around in a bewildered way, rose from the bed and in a dazed manner attempted to push aside one of the physicians. His three attendants, believing him to be delirious, seized him and attempted to force him back to bed, but Mr Hanna's strength, while ordinarily excellent, now seemed herculean, and his opponents were readily worsted Finally he was overcome and securely bound with straps for fear of his injuring himself or others. While now having the physical strength of an exceptionally robust man his mind was a blank as void as though he had just been ushered into the world He saw smelt, tasted and touched but these senses conveyed absolutely no meaning excepting as to mere light and darkness and color Objects space and time were without intelligent perception There was no perspective sense everything irrespective of distance appeared close to his eyes giving him the impression of one great picture An object seen through the window appeared as near as his outstretched hand and he would not have had any hesitancy in attempting to grasp the moon

Sensations of hunger gave rise to great distress, but without arousing the least knowledge of the reason Food placed in his mouth did not excite any sense of its use He made no attempt to either masticate or swallow it and in order to feed him it was necessary to force food back into the pharnyx to cause reflex or involuntary swallowing movements

Bodily movements alone at first attracted his attention and he learned in time to distinguish between movements of his own body and those of other people and things He gazed at moving objects with the wonderment of the young infant and after he had learned to associate movements with life he thought all moving objects living things the swaying of the branches of a tree appearing to him movements of living creatures and the horse and carriage a single living object

He heard conversation or noises as he termed them and in time recognized that by their means people could understand each other and although he had not the least idea of the meaning of a single word he thought he could learn to communicate with others by repeating the noises he had heard Hence he would again and again repeat in his mind these sounds and then repeat aloud words and sentences he had committed to memory but he was surprised to find that he was not understood and for a time he became discouraged Not knowing the meaning of his utterances his speech was of course utterly unintelligible It was not until the lapse of two days that he had learned the real meaning of a single word

By this time he was able to recognize time by the difference between daylight and lamplight and by the recurrence of the three daily meals His education may now be said to have been fairly started He began to understand speak read and learn to walk

Owing to his mental faculties having been highly developed and to his inherent capacity for rapidly acquiring knowledge he learned with amazing rapidity even to the attainment of accomplishments that were unknown in his normal life Thus he learned in a few hours to play the banjo an instrument with which he had had absolutely no experience

For nearly two months he remained in this mentally childlike state gradually but with extraordinary rapidity acquiring the elementary knowledge common to early childhood having absolutely no knowledge of his existence before the accident or of his actual relations to the people about him and developing during this period an entirely distinct personality as different from his normal as the personalities of two people differ His memory was so keen during and after this period that upon his ultimate recovery he was able to give a minute account of his experiences and thus unfold a remarkable history of incidents such as presumably are attendant upon the education of the infant and very young child

The period of second personality lasted for seven weeks and was ended by his falling asleep and awaking as the Rev Mr Hanna he now having absolutely no remembrance of what had transpired since the moment of the accident He thought that the accident had occurred the evening previous and when told that it was seven weeks ago he thought the speaker jesting and the story a huge joke

He had been in New York for some time but he failed to recognize his surroundings and the people who had been in constant attendance for weeks past were absolute strangers excepting his brother the only one he had known in his normal state

In the midst of the conversation he suddenly exclaimed What a funny taste in my mouth you must have been feeding me on tobacco" Before going to sleep he had smoked a cigarette but not having used tobacco for many years and not having any knowledge of the events of the previous evening he could not in any way account for the taste. When asked how he felt, he said "I feel just like Rip Van Winkle." After remaining in his primary state for three-quarters of an hour he fell asleep awaking in his second personality his mental life beginning where it had ceased upon falling to sleep the night before, he not having a vestige of knowledge of what had transpired between the two periods of sleep

From this time on there followed frequent alternations of the primary and secondary personalities, the transition from one to the other occurring without obvious cause and with increasingly greater frequency The alternations were for a time wholly unknown to Mr Hanna, excepting in so far as he was informed by others and owing to the very different memories of the two states more or less serious embarrassments were caused

With the passing of time the frequent alternation of personalities, the gradual acquirement of knowledge during the periods of his second personality, and the increasing information received from those about him of his mental dual existence, there came a moment when he clearly recognised the existence and differences of two personalities or mental lives Struggles of the two for the possession of the body occurred at which times Mr Hanna would be in a dazed state and in neither one nor the other personality What went on in Mr Hanna's mind was quite accurately remembered by him and is well set forth in a statement made by Mr Hanna to Drs Sidis and Goodhart

Mr Hanna stated that while lying upon a lounge in one of these dazed conditions he had engaged in one of the most intense struggles he had ever experienced The two personalities the primary and secondary states rose simultaneously and confronted each other Each of them was the I still they differed from each other The memories seemed to be those of two different persons yet he recognised that both were his He could not choose one because it differed from the other nor could the two be joined The struggle produced great perplexity and perturbation He felt that both were his yet it seemed impossible to unify them One could not be abandoned because both came up constantly before him as though exclaiming We are one though different It seemed as if each said to the other Thou art a mortal foe and yet thou art bone of my bone and flesh of my flesh Each it seemed had for a time tried to crush or suppress the other The question in his mind was which of the two lives he should reject and then the struggle was not so much to choose one as to forget the other both persisting in his consciousness as though each memory was stronger than his will Each memory seemed to be within the same physical being as if there were two bodies alike like twins that had lived entirely different lives or like twins of the same body with tastes faculties and natures very similar The time came when he realised that he must take one or the other personality The decision was difficult and the mental struggle great but he finally decided to adopt both because of the fear and anxiety that the struggle would be repeated again and again and that the mental agony of these recurrences would be too great to endure And so in time the two personalities differing so much were fused into one healthy normal mental individual—into one Ego or I the present Mr Hanna

The passing of the hour permits of but an additional word We are creatures not only of to-day but also of yesterday In the secondary personality of Mr Hanna we found evidence as development proceeded of the presence of his primary state and in the latter state of his secondary state Time and again one state would force itself into the other each for the time struggling for mastery finally one letting go as it were the better or the worse state becoming for the time the Rev Mr Hanna

In each of us the Ego or I is not a unity but a duality a blending of primary and secondary selves of conscious and subconscious mental lives of mental processes that, broadly speaking express the human and animal sides of our natures As one or the other may for a time dominate so are our personalities modified As the speaker is uttering sentence after sentence he is conscious of the occupation of the mind with the phrases of the moment, but beneath this consciousness there lies a most potential mental life or background which while seemingly latent or wholly beyond the field of consciousness or introspection is extremely active a life that embraces memories of past experience of self and countless ancestral individuals. It contains the fundamental structural material or sense-images or memories from which all our thoughts are built and moulded

Our physical peculiarities are heritages that go back into the dim past, and they are expressions of causes that had origin beginning in time unknown, our mental lives are heritages that likewise have come to us

through a countless line of ancestors for thousands of centuries. The impress of our progenitors upon our mental lives is not less than upon our physical lives ***Just as each of us has an Ego that is a blended duality that is readily separable into two different selves, so has each of us a dual immortality—an immortality of*** the *soul that is* ours alone and an immortality of the mind and flesh that *is* transmitted to our offspring and which passes from generation to generation The emotions and thoughts of thousands of preceding generations and the acts of the lives of the barbarians savages semi educated educated and cultured individuals who through the course of time have ultimately given us birth echo and re echo in our beings Their personalities like their bodies have been born and reborn in their children and children's children to be born and reborn for better or worse in ourselves and our offspring

Some Features of Photo-Chemistry*

Are They the Results of Electrical Phenomena

By H H McHenry

The subject of photo-chemistry is one about which comparatively little is known While the applications to ordinary photography are well understood the theory that leads to the chemical action of light is far from being perfectly comprehended.

The photo-chemical process has two phases The production of a compound is one phase such as the production of chlorine knall-gas The other is decomposition, such as the decomposition of hydrogen phosphide with separation of phosphorus This latter phase is by far the more common The chemical action of sunlight such as that shown in the bleaching process the production of green colors in plants, and the well-known action of light used for blue-printing, have been known for centuries Only recent investigations however have taught us that numerous compounds are sensitive to light, and convinced us that here we are dealing with a mutual action between ether vibrations and chemical forces By experiment it is found that the chemical action of light takes place only in special cases as it is held that illumination can exert an influence on the reaction velocity of a system which is in the process of change, or on a system in the state of equilibrium which is in chemical repose

Before discussing the theory of the other vibrations, it might be well to cite a few features of ordinary photography The modern chemical method employed in development rests on what is known as the latent light-action of the silver salts" A gelatine film impregnated with silver bromide is first illuminated and then treated with reducing agents The silver haloid in the plate is then reduced to silver most quickly At the illuminated spots this reduction results in the formation of free halogen, but the nature of the reduction product is not known in all cases On the illuminated spots of the plate small particles of metallic silver are deposited by reduction, their density increasing with the intensity of light, but always in such small quantities that no visible change occurs in the substance of the plate When the plate is put into the developer those invisible silver particles act as nuclei for the precipitation of silver, just as small crystals bring about crystallization in a super saturated solution The denser the silver particles at any spot the denser will be the deposit of silver during development

A valuable aid to photography was furnished in a discovery made by Vogel in 1878 He found that photographic plates may be made more sensitive by intermixture with slight traces of organic coloring substances Also the plates are usually especially sensitive for kinds of light absorbed by particular coloring substances Thus plates may be prepared sensitive to yellow, blue or red, or any colored light This phenomenon is called optical sensitation So far no theoretical explanation has been given for it

As light is thought to be a phenomenon occasioned by ether vibrations, the theoretical consideration of its chemical effects must lie with those vibrations When ether vibrations traverse a material system, they occasion two different results. First, they raise the temperature of the system their energy being partly converted into heat Secondly, they occasion chemical changes, occurring at the expense of some of the energy of vibration The first phenomenon is known as the absorption of light, the second as the photo-chemical absorption of light. Gases, liquids, and solids all respond to ether vibrations, such as the explosive mixture of hydrogen and chlorine, chlorine water which gives up oxygen under the influence of light, and white phosphorus which changes to the red modification, in light, or cinnabar which turns black While photo-chemical action may be produced by any type of ray, it depends on the wave-length of the light used, like ordinary absorption

A set of empirical laws of photo-chemical action, compiled by Eder, serves as an aid to understand the chemical action of light-rays They are (1) Light of every wave-length is capable of photo-chemical action (2) Only those rays are effective which are absorbed by the system, so that the chemical action of light is closely associated with optical absorption, although the converse is not true. (3) According to the nature of the substance absorbing light every kind of light may act in an oxidizing or reducing way The red light has an oxidizing effect, and violet light a reducing effect on the metals (4) Not only the absorption of light rays by the illuminated substance itself plays an important part, but also the absorption of light by a foreign substance mixed with the principal substance for the sensitiveness can be stimulated for these rays which are absorbed by the admixed substance (5) A substance sensitive to light admixed with the main substance and which unites with one of the products resulting from photo-chemical action (as oxygen, bromine or iodine) tends to accelerate the reaction velocity to such an extent that reversal is impossible This may be regarded as a consequence from the law of mass action

As stated above these laws can only be regarded as empirical There are some exceptions notably to (3) Red light exerts a reducing effect in the case of the latent light-action of the silver salts while violet oxidizes organic compounds especially colorless ones These laws were ascertained by means of instruments known as actinometers, which measure the intensity of the chemically active rays The idea of actinometers is a most important one All pieces of apparatus which are designed to measure this intensity, and which collectively depend upon the observed changes which are experienced by substances sensitive to light when under the influence of ether vibrations, are called actinometers The data obtained from actinometers of all kinds must be considered as having a purely individual nature They give only a *relative* measurement of the intensity for if the same kind of light is used the nature and reaction velocity of the chemical process occasioned in each case will vary according to the behavior of the system which is subjected to the action of light Also when the light used consists of rays of different wave length, the data of the same actinometer will by no means be proportional to the intensity of light, as the action of light varies greatly according to its wave-length

It might be well here to consider a few types of actinometers The eye can be considered an actinometer because apparently, its sensitiveness to ether vibrations depends upon certain photo-chemical processes which are thereby occasioned However, the results of visual photometric measurement are not parallel with those obtained by actinometers, and neither results are parallel to those obtained by thermometric measurements The latter is usually regarded as an absolute measure of radiation It would perhaps be more correct to regard the diminution of free energy which is unknown associated with the change of radiant energy into heat as the measure of the intensity of light

A simple form of actinometer is that known as the chlorine knall-gas actinometer It depends on a discovery of Gay-Lussac and Thenard in 1809 who found that when strong light acted on the combining of chlorine and hydrogen the velocity increased rapidly to the point of explosion, and, when weak light acted, it progressed slowly and steadily The method consists in measuring the diminution of a volume of chlorine knall-gas (standing over water, and maintained at constant pressure and volume) as a result of the formation of hydrochloric acid, which is absorbed by the water This actinometer was constructed by Draper in 1843 and, later, improved by Bunsen and Roscoe

These two men discovered the silver-chloride actinometer, in which the time required to darken a photographic paper until a definite "normal" shade is reached is taken as a measure of light-intensity

Another interesting actinometer is the electro-chemical actinometer Two silver electrodes, which have been chlorinized or iodized, are dipped into a dilute solution of sulphuric acid Electromotive force will be established between the electrodes, and as long as one of them is illuminated the current will flow in the solution from the unlighted to the lighted pole The strength of the current is read by means of a sensitive galvanometer, and this serves to determine the intensity of the light Results obtained by this actinometer agree approximately with those obtained in photometric ways This actinometer was constructed by Becquerel in 1839

Attention may now be turned to the work performed by chemically active light One would expect the light to be absorbed to a greater degree when it occasions or accelerates a chemical process than when such is not the case Bunsen and Roscoe found that when light passed through a layer of chlorine knall gas it was much more weakened in its chemical activity than when it passed through chlorine alone In both cases the light is weakened by absorption by the chlorine the absorption by the hydrogen can be neglected But in the first instance absorption is purely due to optical activity and therefore the loss of energy reappears in the heat developed In the second case however an additional fraction of light-energy is consumed in performing chemical work which thus occasions a stronger absorption This phenomenon is called photo-chemical extinction

A word may be said as to the speed of chemical light-action Bunsen and Roscoe found that light usually acts very slowly at first and only attains its full activity after a lapse of time This is called photo-chemical induction Pringsheim succeeded in showing that this phenomenon is due to the formation of intermediate compounds As chlorine knall gas is more sensitive to light when moist than when dry it seems probable that hydrogen and chlorine do not unite directly to form the acid but that a series of intermediate compounds is first formed Also a slight preliminary exposure of a photographic plate renders it more sensitive and an under exposed plate is strengthened by a subsequent exposure

The physical laws which chemically active photographic rays obey are of peculiar interest They are reflected refracted and polarized like other rays their intensity diminishing as the reciprocal of the square of the distance from the point of origin Research work has shown that when light of the same kind is used the photo-chemical action depends solely on the product of the intensity and the duration of exposure It has also been proved beyond doubt that the time required for the development of a normal color on sensitive paper is proportional to the number of light-waves which strike the paper per second

One important difference between photo-chemical reaction and ordinary reactions is that the velocity in the former increases but little in a rise of temperature, while that of the latter increases enormously We are led to believe that light action should not be regarded as a direct loosening of the atoms in a molecule such as that effected by heating but rather the primary effect must be some action on the luminiferous ether and suggests ionization

Now what is the cause of these light-vibrations? The latest authorities maintain that light-vibrations are produced by electric agitations, and that in the chemical action of light we deal with phenomena not far removed from the formation and decomposition of compounds under the influence of the galvanic current That chemical equilibrium is affected by illumination follows from the change in the thermodynamic potential of components by illumination as may be more clearly deduced from the electro-magnetic theory of light It has been proved that electrification and magnetism alter the thermodynamic potential and the action of light-waves is according to the most advanced theories, that of rapidly alternating electric fields From these conclusions we may assume at least until further knowledge of the subject is gained, that the ultimate cause of the photo-chemical action of light lies in electric phenomena

size Architects often hesitate to put large mirrors in new buildings on account of the frequent deterioration by dampness and the emanations from fresh walls Another source of trouble comes from saline air on the sea coast which cause damage to mirrors in these regions For a long time a good method of protection has been sought for not only against dampness but also from such gases in the air as sulphurous anhydride sulphuretted hydrogen and others Direct use of varnish should be avoided because of the presence of bitumen and other substances and moreover varnishes have been found insufficient protection and are not durable The chemist Liebig's method was to cover the silver plating with an electrolytic coat of metal but this very rational plan has up to the present time been limited to small opticians and surgeons mirrors because of the difficulty of applying it on a large scale The present idea refers to mirrors which have been coated with silver by a deposit of that metal on the glass from a suitable bath and the object is to extend the Liebig process to looking glasses of all sizes such as are so widely used in shops and public buildings

Up to the present time it has only been possible to connect the electrolytic current by contacts placed at the edges of the mirrors to be protected which plan had the serious inconvenience of producing deposits thicker at the edges than in the center of the mirror by reason of the great electric resistance offered to the passage of the current by the thin silver coating The center of the glass thus received a very slight covering of copper

The great difficulty has been to multiply the metal contacts direct on the surface of the silvered glass so that the density of current should be uniformly distributed By the direct application of the contact on the surface of the mirrors there was the risk of doing considerable damage to the delicate silver plating the thickness of which is well known to be infinitesimal (about 0.0005 millimeter)

The Declère Gresy and Pascalis process does away with these inconveniences The most interesting and characteristic part of the process is the system of the rheophores which distribute the current by the aid of hundreds of contacts which by simple devices are brought into delicate contact with a silvered mirror and distribute the current equally over the silvered glass

Because of their multiplicity each contact possesses a very limited field of action and as the contact is made by hundreds of points distributed over the glass only a small amperage is delivered at any one place thus avoiding the violent action while dividing the useful effect of this current in a very uniform manner without loss The deposit of copper thus obtained is perfectly continuous and homogeneous and does not admit dampness or any other cause of alteration

The negative rheophore is formed by a sort of comb made up of brass wire teeth each of which makes a contact with the silvered surface, and forms a center of distribution The expenditure of current is very small, and the rods of the rheophore are sheathed except at their extremity in such a way that the electrolytic deposit is laid equally over the surface of the glass.

By this new process it is possible to manipulate as many pieces of glass as the vat will contain, so that one can obtain the maximum of production at the same time with the smallest space The system of anodes used in the process is extremely simple, inexpensive and rapid and offers the advantage of covering only the glass to be treated.

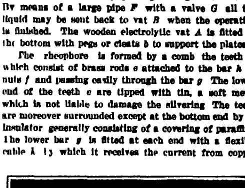
The use of the under reservoir permits the electrolytic vat to be emptied as soon as the operation is over and the mirrors are washed and left to dry in the vat The handling of the glass during the process is thus avoided with the economy of not having to provide a special washing vat

The consumption of electrolytic liquid is also much reduced by the present construction of the apparatus and the active circulation of the bath in the vat by means of a centrifugal pump results a continuous filtering out of the impurities in the bath thus leaving no trace of them on the copper deposit. The cost of the current and of the electrolytic liquid is strictly proportionate to the area of the plates to be coppered

The general operation of the apparatus is simple and regular and essentially practical and the average workman can execute the copper plating perfectly after a few explications and on glass of any dimensions

Description of the Plant.—The apparatus consists of two tanks the top one of which *A* is that used for the electrolysis The other tank *B* generally placed under ground contains the electrolytic solution which a centrifugal pump *C* forces continually to the inlet *D* where suitable guide pieces direct the current toward the surface to be treated The solution passes through vat *A* and returns by an outlet *E* to the vat *B* where all impurities are removed by passing through the filter *a* By means of a large pipe *F* with a valve *G* all the liquid may be sent back to vat *B* when the operation is finished. The wooden electrolytic vat *A* is fitted at the bottom with pegs or cleats *b* to support the plates *c*

The rheophore is formed by a comb the teeth of which consist of brass rods *e* attached to the bar *h* by nuts *f* and passing easily through the bar *g* The lower end of the teeth *e* are tipped with tin, a soft metal which is not liable to damage the silvering The teeth are moreover surrounded except at the bottom end by an insulator generally consisting of a covering of paraffine. The lower bar *g* is fitted at each end with a flexible cable *k* by which it receives the current from copper



General view of coppering plant

conductors *l* which connect with the negative pole of the source of electricity The cable *k* is joined to the conductor *e* by the clamp *m* The bar *g* is rigidly attached to bar *A* and the gears *o* operated by the hand wheel *n* and shaft *p* raise or lower the bar *h*, thus regulating the contact of the teeth *e* with the surfaces that are to be copper plated. The rheophore may be lifted out of the vat as shown in Fig 1 to facilitate the manipulation of the plates

The anodes are formed by copper strips *q*, each strip being fixed to a wooden bar as shown in Figs. 2 and 3 A dynamo *t* generates the necessary current and gives about five volts and thirty amperes per square meter of glass to be coppered. The pump *c* and dynamo *t* are generally placed on the same shaft with the motor *u*

Rangefinders

Of the many instruments designed by the engineer for the more accurate conduct of naval warfare none is of greater importance than the rangefinder In the days of Nelson no such device was necessary To come to grips ships of war were obliged to approach so near to one another that there was rarely any doubt about accurately laying the guns, and any error could be promptly corrected In modern warfare conditions are very different, and a naval engagement of the first order of importance may take place with the units of the opposing fleets separated by miles of ocean. But the engagement, says the London *Daily Telegraph*, can only come to a satisfactory conclusion if the rangefinding

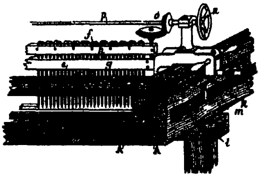


Diagram showing details of apparatus used.

has been accurate and the range within the limits of the guns for an adequate period With projectiles costing some hundreds of pounds apiece, and the possibility of disaster if one of these misses its mark, it is clear that for rangefinding to-day the unaided human eye is no longer of the value it was in the days before the coming of steam and the ironclad

Since the eighties therefore much ingenuity has been directed toward obtaining an instrument which at a glance, would indicate correctly the distance of any object within range of vision one of the latest types being an anti aeroplane instrument This is so mounted that the base of the instrument swings in a vertical plane and the eyepiece is situated in the line of the trunnion thus enabling the rangetaker to make observations with comfort upon objects at practically all altitudes The mountings of such rangefinders are specially designed to enable a rapidly moving object to be kept under continuous observation

A single observer rangefinder may be regarded as consisting of two telescopes mounted in a common frame with the two objectives situated one at each end of the frame and with the eyepieces at the center suitable reflectors being provided at the objectives to direct the beams of light along the frame toward the eyepieces and the whole arrangement being such that the combined telescopes may be simultaneously directed on the same target The rangefinder itself forms the base of a triangle having at its vertex the object, the range of which is determined by measuring the parallax i e the angle subtended by the base of the instrument at the object. Two beams of light from the distant object are received by reflectors at the ends of the base and are transmitted through two objectives toward the center of the instrument, where another pair of reflectors placed one over the other reflect the beams outward through the eyepiece Each objective forms an image of the distant object in the focal plane of the eyepiece and the observer therefore sees in the field of view two images which depending upon the type of instrument used may overlap one another or be separated by a fine separating line.

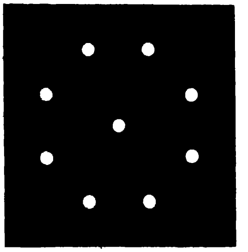
Optical or mechanical devices are adopted in rangefinders of this class for altering the course of one or other of the beams of light within the instrument, so as to bring the two partial images into correct coincidence or alignment, and a scale is provided for indicating the distance of the object, the scale or its index being moved by the gear used for bringing the images into alignment.

Plant Only Certified Potatoes

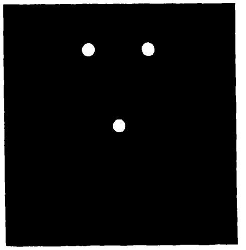
In some sections of the country potatoes are infected by a powdery scab and as a result these districts are quarantined by the Department of Agriculture, which has issued a warning to farmers and others that in procuring seed potatoes to use only such as come in sacks bearing the white label of the Potato Inspection Service Table potatoes for the general market are shipped in bulk and the car alone bears a blue certification tag, so it is not desirable to buy ordinary eating potatoes for seed purposes. Some dealers are said to be selling eating potatoes for seed purposes, and while they are not violating any law, those who buy this kind of seed are liable to find they have introduced a dangerous disease and are liable to quarantine. The white seed certificates relate only to freedom from powdery scab and not to the quality of the potatoes, still those in certified seed sacks are apt to be more carefully selected than the average stock.

Guide Lights on Aviation Fields*

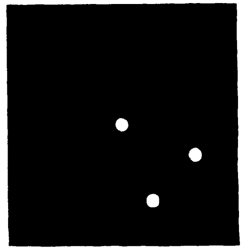
The aviation field at Johannisthal, Germany, is to have an underground lighting system which will indicate for the nocturnal aviator the best place for landing and the direction of the wind. The lights are inclosed in iron boxes, which are covered with round panes of very thick glass and are sunk in the ground to their tops. Eight such boxes are arranged at equal distances in a circle the center of which is marked by a ninth box. Each box contains a red and a white electric light, and the current, conveyed by underground cables can be switched into either light by hand or by an automatic device operated by the wind. The direction of the wind, which by day is shown by a canvas imitation of an aeroplane landing against the wind, is correspondingly indicated at night by three white lights. Two of these lights, marking consecutive vertices of the octagon, represent the wings of the aeroplane, while the third, at the center represents the tail. The other five lights are red.



All lights are white in a dead calm



Arrangement of lights for a north wind



Arrangement of lights for a southeast wind

Of the eight principal points of the compass that can be indicated in this way that one is shown which most nearly represents the actual direction of the wind. The landing is made against the wind by steering the aeroplane over the central light and midway between the other two white lights. In a dead calm all of the lights are white and the landing can be made in any direction. In the accompanying illustrations as in maps the top is north, the right side east, etc. The white lights are represented by white circles, the red lights by shaded circles.

The Function of the Earth in Radio-Telegraphy†

A lecture on the above subject was delivered on Friday evening November 13th by Dr. J. A. Fleming to the members of the Wireless Society of London at the Institution of Electrical Engineers. Dr. Fleming said that the present period of enforced inactivity for all loyal radio telegraphists except those engaged at the seat of war offered an opportunity to reconsider some of the purely scientific questions involved in the art. He proposed therefore to discuss the function of the earth in radio-telegraphy. Apart from the disputed question whether the aerial wires should preferably be earthed at the base or connected to an insulated balancing capacity, it was well known that the nature of the soil or surface between the transmitting and receiving stations had a great effect on the signal strength. This effect depended much upon the wave length. Thus Dr. L. W. Austin had shown that the ground to the north and northeast of Newport, Rhode Island, U. S. A. exercised a powerful absorption on radio-telegraphic waves of about 1,000 meters wave-length. Experiments made between Brant Rock wireless station and the United States cruiser "Birmingham," lying at Newport showed that whereas electric waves of 3 750 meters wave length suffered little or no absorption in traveling over the forty-five miles other than that due to the normal space decrease of energy, waves 1 000 meters in length lost 95 per cent of their signaling energy in passing over the same district.

Dr. Fleming first gave a brief mathematical discussion showing the manner in which the gradual penetration of an alternating current into a conductor can be explained. It is well known that high frequency electric currents are confined to a thin skin or layer of the surface of metallic wires. In the case of copper this skin has a thickness of about 0.25 millimeter for currents of a frequency of one million. In the case of iron the skin for the same frequency is about 0 02 millimeter.

An elegant experiment was shown by Dr. Fleming with his cymometer to illustrate this surface flow of high frequency currents. An oscillation circuit was arranged in which high frequency currents were generated and these were detected by placing alongside a cymometer having a Neon vacuum tube as a detector of secondary oscillations in its circuit. In the primary oscillation circuit were inserted successively small spirals of copper brass iron and galvanized iron all having the same size and same number of turns. The oscillations in the cymometer circuit were indicated by the brilliant glow of the Neon tube. When the iron spiral was inserted the Neon tube did not glow because of the damping of the oscillations caused by the energy absorbed to magnetize the iron. The galvanized iron spiral behaved however just like a copper or brass spiral because the oscillations did not penetrate through the thin layer or skin of zinc into the iron. If however this zinc was oxidized or broken then the iron core exerted its effect in damping the oscillations.

Dr. Fleming then explained that when a radio-telegraphic wave passes over the earth it penetrates to some extent into it, and also loses amplitude owing to the absorption of wave energy by the soil. The depth of penetration or depth in which the forces attenuate to ϵ or to 0 368 of their surface value and the horizontal attenuation or distance in which the surface values decrease to the same fraction of their original value can be calculated as shown by Dr. Zenneck when the values of the soil conductivity soil dielectric constant and frequency are known. Thus taking the generally accepted values for sea water for waves 1 000 feet in wave length the penetration into the sea is at most about one meter. In the ordinary dry soil it may be 100 or several hundred meters. There is a certain soil conductivity and wave-length which gives the maximum attenuation of the wave over a given distance.

The calculation of the depth of penetration and attenuation of the wave with distance can be made when this soil conductivity and dielectric constant is known. Recent researches have shown however that the conductivity of imperfect insulators for alternating currents is much greater than for direct currents. Dr. Fleming referred to researches by himself and Mr. Dyke for proof of this fact. Lately he said Mr. Bairsto had continued this work in his laboratory for currents of extra high frequency of one or more million and found their dielectrics had a maximum conductivity for a certain high frequency. The inference from this was that the earth was an incomparably better conductor for the high frequency curves used in radio-telegraphy than for ordinary low frequency or steady currents. Dr. Fleming then went on to consider the propagation of an electric wave over the earth's surface and pointed out that Sommerfeld had shown that when a Hertzian oscillator had one half connected to the earth there would not only be space waves through the dielectrics (air and earth) but a surface wave along the surface which would consist in longitudinal electric currents propagated as a wave motion along the surface. Dr. Fleming pointed out that this surface wave might be the explanation of the well known facts that signals from long distance wireless telegraph stations can be picked up and detected without any high receiving wire merely by connecting one end of the receiver to the earth and the other to any insulated mass of metal in the interior it may be, of a house.

Passing then to the consideration of the diffraction of long electric waves round the earth Dr. Fleming gave a brief account of the state of the theories advanced by Poincaré, Nicholson, Macdonald and Rybczynski. These agreed that the amplitude of an electric wave sent out horizontally from any point on the earth's surface diminished according to an exponential function of the distance and wave length. The last named analyst had shown that this function was of the form $\epsilon \quad \sqrt[3]{\lambda}$ where r is the distance of the sending and receiving stations and λ is the wave-length. Actual observations by Austin over distances up to 1 000 miles had led to an empirical formula differing only in that $\sqrt{\lambda}$ appears instead of $\sqrt[3]{\lambda}$.

The bulk of the evidence so far collected as to long distance transmission showed however that true diffraction of space waves or even the surface waves could not contribute more than a moderate fraction perhaps not 20 per cent to the total observed result. The chief part of the effect for distances of 3 000 to 4 000 miles must be contributed by space waves which had reached the receiving station indirectly that is after reflection or refraction at the surfaces of layers of high altitude ionized atmospheric gases in the manner explained by Heaviside and by Eccles.

The great variations in signal strength taking place from day to day in long-distance wireless intercourse proved that this must be the case.

In conclusion Dr. Fleming exhibited a chart showing the variation in the strength of the signals received at University College London from the Eiffel Tower station in Paris at 11 A. M. each day during last July prior to the outbreak of war. The sudden falling off on certain days was remarkable. Dr. Fleming said that the further examination of the cause of these variations was one of the chief objects of the British Association Radio-telegraphic Committee which was appointed at Dundee in consequence of a suggestion made by him and that as soon as the present calamitous world war came to an end it was hoped these researches might be resumed.

Concrete Wine Cellars

In the region of Champagne in France the wine in bottles is stored in vaulted cellars which are hollowed deep down in the chalk strata but it is observed that cellars of this kind are not always of the healthiest for infiltrations of water are likely to occur. This not only has a bad effect on the quality of the wine but may give rise to a cave-in of the roof. Reinforced concrete comes in here to furnish a solid vaulting that does not depend on natural conditions and recent structures were put in with a comparatively light vaulting and straight walls with concrete flooring as well. The result is a watertight construction which can be kept perfectly clean. An example is seen in one of the cellars at Epernay where the reinforced concrete shell vault follows the outlines of the chalk cut cellar but there is left an air space all around of 4 to 8 inches thick and an air circulation is produced by making suitable openings to the outside. The inside of the vault or cellar has no connection with the exterior part, and is thus kept dry and in the best condition.

Preserving the Forests

Great areas of valuable timberlands are destroyed by fire every year and not only is this an immediate loss but the effects will be felt more severely as time passes. The Forest Service of the Agricultural Department is doing splendid work in fire prevention which can be appreciated by facts recently published in relation to what was done in the Boise national forests in Idaho during the past summer. Thirty fires occurred in this region yet twenty eight were held down to less than ten acres and of these fifteen were less than one quarter of an acre. The supervisor says this success was due to a lookout tower and to efficient telephone and heliograph service.

"Suction" Between Passing Ships—I*

Important But Little Understood Forces Affecting the Motion of Vessels

By Sidney A. Reeve, M.E.

"SUCTION" is a term commonly applied by pilots to at least three distinct hydraulic phenomena associated with moving vessels, between which phenomena they distinguish most vaguely, if at all. These three quite independent actions are

1. The direct impulse embodied in the streams of water projected astern by screw or paddle, independently of any motion of the ship itself.

2. The direct effect of the mass of water which follows a ship bodily when it is moved slowly through restricted waters.

3. The indirect, or lateral pressure, effect of the fore-and-aft acceleration of the water displaced from bow to stern during normal motion through the water at full speed.

Of these, the first two are most simple and obvious, hydraulically speaking, because there the force exerted is aligned with the water's motion. In the case of the last, the force developed hydraulically acts at right angles to the line of the water's motion. The first two need no explanation, and have nothing in common (speaking scientifically) with the third. They play an insignificant part, if any at all, in the majority of "suction" collisions, and are mentioned here chiefly for the purpose of eliminating them from further discussion. They are of frequent occurrence in the daily handling of shipping about crowded wharves, and for want of another name, or in lack of official definition, they are frequently called "suction" by the (American) Admiralty Courts; but because they are seldom of sufficient violence to be of importance, and because they are more of the nature of a "puff" than a "suck" the term "suction" will be used here as excluding them.

Historically speaking, while the science of hydrodynamics has been developed chiefly by British—or, at most, European—students, yet the recognition of suction as a feature of importance in navigation has arisen virtually exclusively in American experience. The sources of information are the books and the Admiralty Court records. Previous to the Olympic-Hawke collision in 1911 there was no literature on the subject known to the writer, excepting Taylor's paper of 1909, describing his Washington experiments. Search of the British Admiralty records by deputy discloses not a single reference to the subject. Marsden's "Collisions at Sea" (London, 1910) makes only a single reference to "suction," saying.

"A vessel will be held in fault if, without necessity, she navigates so close that . . . . she is affected by the wash or suction of the ship ahead and will not answer her helm,"

referring by footnote to the American cases of the McCandless, Mariel, Brookton, and Chicago. No search of French or German court records has been made, but the principal German work devoted to ship collisions ("Der Zusammenstoss von Schiffen," Dr. Richard Prien, Berlin, 1899) makes no mention of the subject, which could hardly have happened had it ever been discussed by the German, or even by any European, courts.

In American waters the earliest instances of ship-action which were probably suction, although not given that name, occurred in 1846 and 1847, in the "Naugatuck"-"Rhode Island" and "Governor"-"Worcester" collisions. By 1869 the phenomenon had found official name, as "suction," in the "Narragansett"-"Providence" collision. From that time forward the appearance of the thing was frequent, albeit at irregular intervals. In 1871 are recorded two cases, in 1877 two, in 1880 five, in 1883 one, etc. All of these occurred in restricted inland waters. In 1885 occurred the first case involving Atlantic liners, when the "Aurania" and the "Republic" came together by suction outside Sandy Hook (but not in deep water).

Excepting possibly the records of the Naval Courts of Inquiry, which are inaccessible, the sole source of data as to actual cases of suction collision is the testimony before the Admiralty Courts. This testimony, it must be understood at the outset, is almost universally incompetent and contradictory. England's sole experience, the "Olympic"-"Hawke" case, was merely typical in this respect. The trouble is not that the witnesses are incompetent as navigators. The trouble is that navigation normally makes no demand for the estimate of the distances in feet or yards. The pilot is accustomed to gauging his distance from outlying buoys or other ships in terms of his vessel's speed or rate of swing, but not in feet. Again, when called upon afterwards for the data essential for an analysis of the collision, he can give, instead of systematic observations or estimates, only his subconscious guess as to what must have been the conditions in order that the known results should have followed, which he does in perfect sincerity. Or even if estimates were actually made, they must have been made at times of great excitement and responsibility, when positions were altering rapidly, and when the pilot's mind was properly occupied with other things.

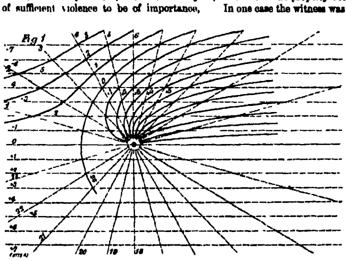
In one case the witness was the captain of a prominent trans-Atlantic liner, a man of dignity and experience. As he testified, the writer plotted the ship's position on a large scale-chart. Had the statements been correct, the ship must have been aground all the way down the harbor. Yet so obvious was the skill, experience, and sincerity of the witness that even opposing counsel made no attempt to impeach his statements. Both sides accepted the testimony as competent to prove that his ship was well over to that side of the channel on which he (virtually) testified that she was aground. In another case the court found, from the combined testimony of competent witnesses, that it was a physical impossibility for a collision to have occurred; but since both vessels were injured the hypothesis as to the facts is necessarily a compromise which includes a collision.

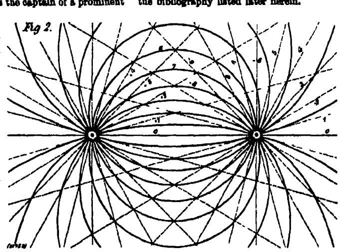
For all these reasons the formation of any accurate deductions as to the distance or angle at which suction becomes an overwhelming force is an impossibility, even for any one case. When the influence of such widely varying factors as ship-model, speed, sea-bottom, etc., is included, it becomes obvious that any hope of securing from experience or theory a *quantitative* law of suction must be abandoned at the start. But even without this, a *qualitative* understanding of the forces at work in "suction" can be of the greatest value in warning pilots as to the general conditions under which it is liable to occur, and as to where a larger margin of caution than usual is needed. For such a qualitative understanding of "suction" a brief incursion into theoretical hydraulics is necessary.

Stream-lines: "Sources" and "Sinks."—Imagine a body of water of uniform depth and unlimited lateral extent, in which is placed vertically, and extending from bottom to surface, a straight pipe of small diameter. Imagine the sides of this pipe everywhere perforated with many small holes, so that it can discharge or take in water on every side throughout its entire length. Let it be connected at the foot with some unlimited reservoir of water below the sea-bottom, so that it can draw water from this reservoir or discharge into it to unlimited extent, just as a "grounded" wire can draw electricity from the earth, or discharge into it, without limit. Disregard all question of friction of flow within the pipe, so that the capacity of the pipe for handling water is independent of its diameter, the speed of flow being anything imaginable. Therefore, for convenience, let the pipe be represented, in plan, by a geometric point.

Such a point as this, when drawing water from below and discharging it into the sea, is called a "source." When the flow is in the opposite direction it is called a "sink." Thus a source would radiate water horizontally in the sea, away from it as a center, in all directions equally. Conversely, a sink would draw water to it horizontally in all directions.

"Stream-lines" are mathematical functions of the volume of flow of water which can be represented conveniently and accurately on fields of co-ordinates, and which can be added, subtracted, etc., like other mathematical quantities. They may be of any imaginable form, and may be either of two or of three dimensions. For present purposes, no presentation of the mathematics of stream-lines is needed; nor do we need the three-dimension functions, which are much more intricate to handle than the two-dimension. Only those particular forms of two-dimension lines which pertain to the analysis of "suction" will be mentioned, and for an understanding of their mathematics the reader is referred to the bibliography listed later herein.





From a "source," or toward a "sink," radiate straight stream-lines, like the spokes of a wheel. Physically speaking, each stream-line represents a sector of flow of water, measured from some radius taken arbitrarily as a zero axis around to the radius or stream-line in question. Therefore the angle between zero axis and stream-line is the mathematical measure of its quantity, and this quantity of flow is the same at all distances from the center. Any convenient angle may be taken as the unit angle, or an arbitrary quantity of flow may be taken as the unit. According to the number of such units stream-lines radiating from a "source" or "sink," the latter is said to have different "strengths."

In a canal of uniform, rectangular cross-section, in all portions of which the rate of flow was the same, the stream-lines would be straight lines parallel with the banks. The distance from the bank would be the mathematical quantity of the stream-line.

Fig. 1 shows the addition of two such sets of stream-lines, resulting in a third set. The radial stream-lines are given numerical values, from "zero," at the axis of the figure, around to "24" for an angle of 360 degrees. The parallel lines are given similar values—positive below the axis, and negative above. Selecting any desired value for a resultant stream-line, the line can be located as passing through the intersection of each pair of original lines the sum of whose values equals the desired value. Resultant lines are thus found having values ranging from "zero" for the stream-line crossing the axis at right angles and rising above it, increasing around to the right until the same line below the axis has the value "24." From the "zero" resultant line above and to the left are lines having negative values. Below and to the left are those having values above "24." Both positive and negative series extend indefinitely away from the center of the figure.

Such a set of resultant stream-lines would give the effect of placing a "source" or a "sink" in a uniform

* Reproduced from *Engineering*

current, the current flowing to the right if the point be a source, or to the left if it be a sink Fig 2 gives the stream-lines resultant from compounding a source with a neighboring sink in still water Fig 3 gives the lines resultant from compounding a source and a sink in a uniform current, or from moving a source and sink together through still water (The resultant lines are restricted for clarity to one out of the four quadrants of the figure but they obviously exist alike in all four quadrants) The latter condition gives us our first mathematical approximation to the displacement of water from bow to stern of a moving ship

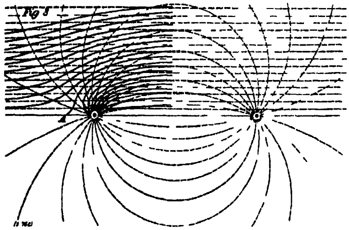


Fig 3

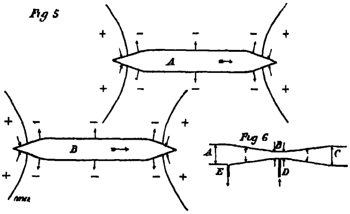

Fig 5
Fig 6

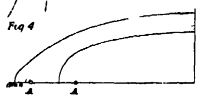

Fig 4

In Fig 3 the stream line A when completed, gives the first suggestion of the water line of a ship If we imagine the water encompassed by this stream-line in a sea of uniform depth equal to the draught of a ship to be solidified without change in volume this solid would form a ship body having vertical sides and a rectangular cross-section and the motion of this ship body through the sea at the speed represented by the parallel lines of current would develop stream lines in the surrounding sea which would be mathematically equal to those developed by the combination of moving source and sink The source represents the water thrown off by the bow to open passage-way for the ship while the sink represents the regathering of this water under the stern to fill in the trough cut by the ship's passage

The 'source-and sink' method thus opens a door to the exact analysis of the displacement of the sea by a passing vessel It is a method to which much time has been given by many able men. Originally it was cultivated as a means for designing ships of perfect form which should be capable of waveless progress through the water with minimum resistance but its very limited value for this purpose was realized long ago Now the problem of "suction" offers it a new application

By far the most ingenious and the cleverest development of the stream-line theory for actual ship-models has been contributed by United States Naval Constructor Taylor He read two papers before the Institution of Naval Architects (British) one, in 1894, on "Two-dimension Stream-lines," and the other on "Three-dimension Lines," in 1895 Taylor conceived the idea that if it be permissible to compound the stream-lines from two finite sources and sinks as Rankine did or from several finite sources as other computers did afterwards it is equally permissible to increase the number of sources and sinks indefinitely each source becoming correspondingly reduced in strength until an infinite number of infinitesimal points form the basis for integration into stream lines In other words the fore half of the ship is represented by one (graphical) function of sources of varying strength while the after half has a similar function of sinks By a very ingenious method of graphical integration without which the computation of even a few finite sources becomes intolerably burdensome the stream lines are deduced from these assumed functions For the details of Taylor's method the reader is referred to his papers[1]

Mr Taylor made tests of the force of suction between two ship-models towed in fixed parallel position in the testing-tank at Washington in 1909 and these were reported to the (American) Society of Naval Architects and Marine Engineers He repeated similar tests before the British Admiralty Court sitting on the case of the Olympic - Hawke collision during the winter of 1911 1912

The author's connection with the development of the theory of suction began in 1908 when he was called upon to explain the suction collision between the United States and the Monterey coastwise liners in New York Bay The trial being already under way when he was first approached, there was time only for the preparation of crude diagrams But in connection with the Denver Lehigh case later that same year and in the case of the Parima and the Prinzessin Irene still later, these diagrams were got up more carefully They discussed merely the general outline of the constrained wave that for one ship being drawn on transparent cloth, so that it could be slid over that for the other ship, to show how suction forces were developed by those two outlines getting into and out of phase This so far as the author is aware was the first publication of any general theory of suction Yet it is proper to state no further developments to which the writer has been able to carry this general theory toward exactness in terms of particular ship-lines have appreciably altered this first explanation which was based upon hydraulic facts which are familiar to every pilot and ship owner

II SHIP WAVES AND SEA CONTOURS

In all the earlier writers and persisting in some textbooks to the present day there is a confusion as to classification of the several sorts of ship resistance which must be cleared before the navigator taught in those years can understand suction clearly These resistances are now distinguished as (1) skin friction, (2) wave-making, with sometimes a third, eddy making which is really a part of (1) At present these resistances are mentioned only for the purpose of excluding them from the argument Suction depends solely upon the existence about every moving ship of (3) the constrained wave which is quite distinct from the bow stern and echelon waves of the usual analysis of the wave-making resistance But it was not until 1898 that there appears in the papers of the Institution of Naval Architects (British) any realization (by B Schildrop of Bergen) that the 'constrained wave' is distinct from those other resistances in cause as well as in character

The constrained wave of a ship is not a true wave at all The true waves are classified as (a) bow waves (b) stern waves and (c) echelon waves All of these are visible disturbances of the sea surface which travel away from the ship by their own inertia, when once started and with which all seafaring people are familiar

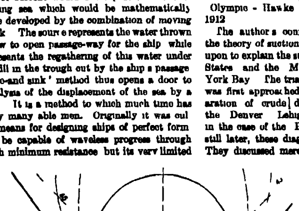

Fig 7

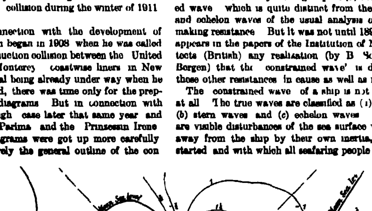

Fig 8

The 'constrained wave' on the other hand is often invisible and usually needs to be looked for even when visible It consists of a wide low mound of water which the ship piles up ahead of herself and which accumulates until enough surplus pressure is gathered to start the water into motion aft beneath or around the hull Its height is very low like a ground swell, but its bulk is tremendous Its trough may be seen on either beam amidships, and at the stern rises a second low crest Although it is relatively to this that the true waves

[1] On Ship Shape Stream Forms by D W Taylor Transactions of the Institution of Naval Architects 1894 vol xxxv page 385 Engineering vol lvii page 410 On Solid Stream Forms and the Depth of Water Necessary to Avoid Abnormal Resistance of Ships, by D W Taylor Transactions of the Institution of Naval Architects, 1895 vol xxxvi page 234 Engineering vol lix page 489 and 497

rise visibly, yet the "constrained wave" itself is visible about every fast vessel, and in tugs it often rises a fair fraction of the freeboard, the hull "squatting" visibly into its trough.

This "constrained wave" may be explained in terms of the stream-line analysis. The two-dimension stream-line presupposes that the sea is of uniform depth, that the ship's sides are everywhere vertical, reaching to the sea bottom, and that the sea is covered with a thin sheet of rigid ice, strong enough to prevent any vertical alteration of sea surface. This ice may be supposed not to interfere with the motion of the ship, or the ship may be a submarine just reaching from the bottom to surface. Under such conditions alone would the motion of the water displaced by the ship's motion be purely horizontal Under such conditions the increase in pressure necessary for accelerating the water away from the bows, and that engendered by its arrest at the stern again, would remain purely *pressure*, confined by the rigid ice against rising in surface-waves.

But in actuality there is no ice. The increase in pressure ahead of and astern of the ship actually occurs, but it is partially relieved at the sea-surface. A readier means for the release of the water than *horizontal* acceleration is *vertical* acceleration. The water gets out of the ship's way by rising vertically from either bow, in waves. The most striking instance of this is the tiny jet of water often appearing right at the stem of river steamers. This water is displaced by a hull of rectangular outline, but small dimensions (the stem), which is propelled at disproportionate speed by a relatively enormous power; hence the vertical acceleration of the water is exaggerated.

But a more common form of vertical acceleration is seen in the "bow waves," which rise on either bow, and repeat themselves in a series extending obliquely aft along lines making angles of about 23 degrees with the ship's course, ultimately merging themselves with the echelon waves. From the stern trail away two similar series of "stern waves," but much smaller than the bow waves. On either beam, and all across the wake, spreads the procession of broad, low echelon waves. All of these are due to *vertical* acceleration of the water due to the lack of constraining ice, and all of them constitute deductions of energy from the "constrained wave," which is normally due to purely horizontal acceleration of the water

In actuality, too, there is always room for some water to escape beneath the ship's bottom, instead of spreading out laterally. In deep water this is the path for most of the displaced water. But in shallow water this path is cut off. Even where there is a foot or so of water between hull and sea-floor this space is useless for passage of water, because of the turmoil of eddies. And since the force of suction is developed only by an acceleration of water, which finds its pure and best expression only when the ship extends to the bottom, while the sea-surface is constrained by imaginary ice, these are the conditions which will be assumed throughout the discussion. All question of bow waves, echelon waves, etc., is thus eliminated.

In such a sea let there be held a vertical pole, extending to the bottom, which is then moved horizontally. This is like a vertical pipe having perforations in its sides, the side looking toward the course ahead being a "source," while the after side is a "sink." Imagine two lines drawn on the chart through the point representing such a pole, at angles of 45 degrees with its course, forming four quadrants one ahead, one astern, and one on either beam. The theory of stream-lines shows that in the quadrants ahead and astern the sea-pressure is greater than normal, so that, if there were no ice present, the sea-surface would be elevated above normal. In the quadrants on either beam, conversely, the sea-pressure is less than normal, so that, in the absence of ice, the sea-surface would be depressed. The 45 degree lines are the loci, or contour lines, of mean sea-level.

Such a four-phased distortion of the sea-surface actually accompanies every ship. Its exact form is influenced by the ship's model and by the energy leaking away in vertical wave-forming acceleration. But, in essence, it is always there, approximating the 45-degree lines in mean sea-level contour It is due solely to horizontal motion of the water, and it constitutes virtually the sole force causing suction.

This "constrained wave" is not properly a wave at all. It does not proceed by its own inertia, but is held constrained, as to form and magnitude, by the environing solid ship and sea-bottom It is stationary relatively to the ship. Its inertia plays no part so long as the depth remains constant. When that varies, however, the inertia of the constrained wave becomes the most powerful force controlling the ship. For while its head is low—so low as usually to be invisible—yet the mass of water involved is enormous. It extends away from the ship indefinitely, decreasing with distance, but still perceptible at several ship-lengths away.

The form of this constrained wave is markedly distorted near the ship, away from the simple 45-degree lines of mean sea-level developed by the pole, by the lines of the ship. It will be necessary to trace further in detail these influences before the constrained waves of actual ships can be studied for suction purposes.

Every moving ship acts approximately like the vertical pole just imagined as moved horizontally through the water—viz., to distort the sea-surface about it in four quadrants, demarked by oblique 45-degree lines through its center of displacement. The quadrants ahead and astern exhibit surplus pressures, or elevations, of the surface above mean sea-level. The quadrants on either beam show deficits below mean sea-level; but in the case of the actual ship its elongated form distorts the 45-degree lines near the ship into curves of a hyperbolic form, asymptotic to the 45-degree lines, meeting the hull on either bow or either quarter.

In Fig. 5 are shown two ships in water-line plan, *A* and *B*, overlapping each other on parallel courses. The hyperbolic contours of mean sea-level are shown extending from either bow and quarter; the plus and minus signs indicate the surplus and deficit of sea pressure in the neighborhood of each ship, while the net horizontal pressure upon the hull is shown by arrows—an arrow heading toward the hull indicating surplus, and one heading outwardly a deficit, of pressure. The ships will be assumed to be moving toward the right, although the curves would be the same (in this particular case) for motion in either direction.

Without attempting now to indicate the exact form of these curves, which will be discussed later, it is plain at a glance that the two sets of plus and minus signs must cancel each other, to some degree at least. Thus ship *A* will have its lateral pressures along its starboard bow *increased* by the influence of *B's* forward quadrant of surplus pressure, while the pressures along *A's* starboard quarter will be *decreased* by the influence of *B's* port lateral deficit of pressure. Since the normal sea pressures along *A's* port side are virtually unchanged by *B's* presence, *A* will feel a tendency to swing to port.

Following the same reasoning as to the effect upon *B* of *A's* starboard and astern quadrants, it appears that *B* must feel a tendency to swing to port also. But whereas *A's* swing in response to these forces carries her away from their origin and decreases the danger of collision, except with objects on *A's* port hand, any slight response of *B* to these forces will very rapidly exaggerate them and accelerate her approach to *A's* quarter.

To the engineer, the situation may be clearer if explained in terms of the familiar Venturi meter, a diagram of which is given in Fig. 6. In the Venturi any surplus pressure existing within the conduit at either end, as indicated by the arrows, is altered more or less into a deficit at the "throat" *B* by the restricted diameter, and the consequent acceleration of the water at this point. If a branch pipe *D* be connected at this point, the deficit may be enough to draw fluid in through this pipe, although water might flow outwardly with force at *E*. Or, if the Venturi be made of flexible material, when the flow has reached a certain velocity the deficit of pressure at *B* will cause the walls to collapse; and this collapse will be sudden and violent, in unstable equilibrium.

Now the space between the two ships of Fig. 5 offers the most direct pathway for the water which, displaced by both vessels, must get from ahead to astern by some way or another. But it forms a *restricted* pathway, with gradual convergence and divergence of solid walls on either side of the "throat." In all this it is quite like a Venturi. But if ship *B* swings a bit to port it creates a situation quite like the first "give" of the throat of the flexible Venturi—the forces engender their own acceleration, in unstable equilibrium, and the motion, once started, accelerates rapidly to a sudden and violent end.

Since the situation of Fig. 5 is usually created by a larger, faster vessel overtaking a smaller, slower one, the latter finds itself first in the *A* position; but this is the position of less danger and is often passed without mishap. But when the smaller vessel has dropped back into the *B* position it is in the greatest danger. The majority of suction collisions occur in this position, the overtaken vessel suddenly swerving uncontrollably—usually in defiance of a hard-over helm, and often against reversed engines—into the quarter of the other vessel.

Usually, of course, the larger vessel is unaffected by the forces engendered mutually between the two; but sometimes it is the larger vessel which is the slower one. Indeed, the recorded instances of suction seem to include every conceivable combination of circumstances which could set these forces at work, with various results. Frequently the ship in the *A* position is driven off her course enough to collide with other vessels, or with a bank. In one instance, a large freighter going down New York Bay, when overtaken by a liner, was swung eight points off her course by this repellent component of the "suction" forces—fortunately having sea room enough to check her way before running aground—but was left in that position helpless until the liner was well by.

For it is obvious that the forces created by these "constrained" waves following and preceding the ships can easily be far greater than any of those ordinarily relied upon for maneuvering. While the altitude of the constrained wave is slight, its extent covers an area of ship-side which is enormous when compared with the rudder surface. Indeed, the difficulty in connection with suction is not to explain it, but to explain how it is that so many ships pass closely without its becoming an overwhelming factor. The most frequent answer is, *depth of water*. It requires no mathematics to show that this Venturi-like restriction of waterway between the two ships is much worse in shallow water than in deep. But suction collisions sometimes occur in water which, while not very deep, provides enough space beneath the hulls to pass a good deal of water; while in quite shallow water vessels often pass very close in safety. To answer these questions the exact form of the constrained wave needs further consideration.

(To be concluded.)

SCIENTIFIC AMERICAN SUPPLEMENT

Founded 1876

NEW YORK, SATURDAY, JANUARY 9, 1915

Published weekly by Munn & Company, Incorporated
Charles Allen Munn, President; Frederick Converse Beach, Secretary; Orson D. Munn, Treasurer
all at 361 Broadway, New York

Entered at Post Office of New York, N. Y., as Second Class Matter

The Scientific American Publications

Scientific American Supplement (established 1876)	per year	$5.00
Scientific American (established 1845)	"	3.00
American Homes and Gardens	"	3.00

The combined subscription rates and rates to foreign countries, including Canada, will be furnished upon application

Remit by postal or express money order, bank draft or check

Munn & Co., Inc., 361 Broadway, New York

The purpose of the Supplement is to publish the more important announcements of distinguished technologists, to digest significant articles that appear in European publications, and altogether to reflect the most advanced thought in science and industry throughout the world.

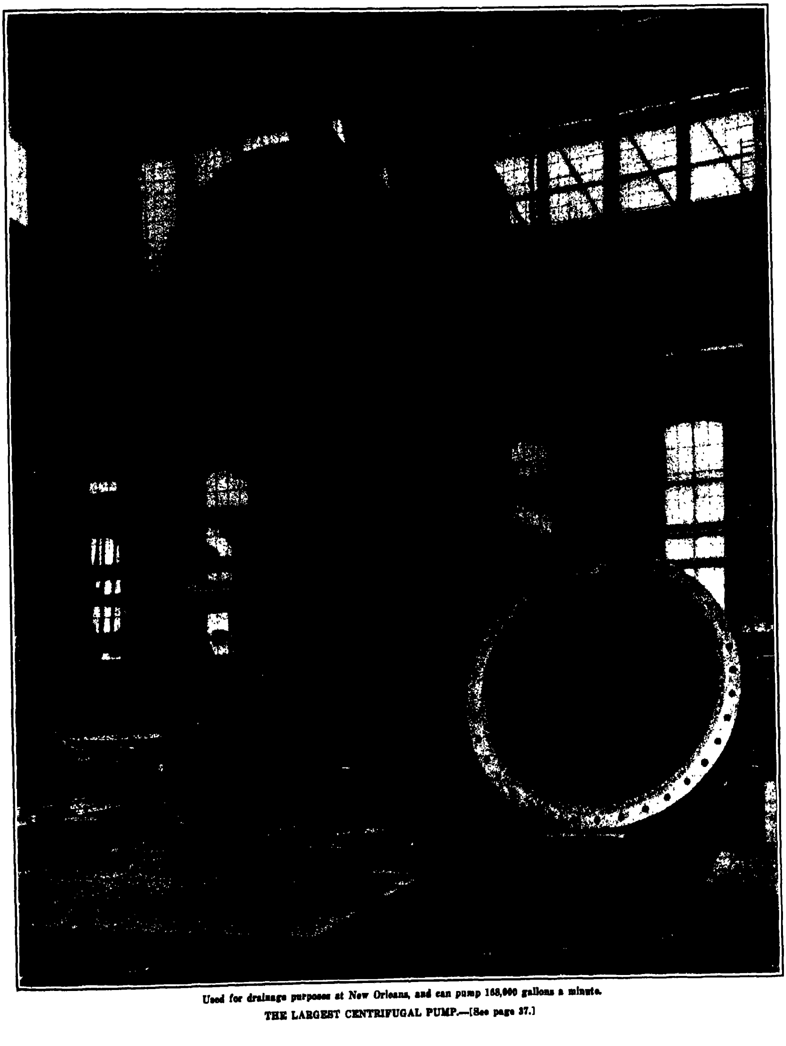
$5.00 A YEAR



Used for drainage purposes at New Orleans, and can pump 168,000 gallons a minute.

THE LARGEST CENTRIFUGAL PUMP.—[See page 37.]

Ozone in Ventilation*

An Exposition of Faulty Methods of Investigation Heretofore Employed

By J. C. Olsen and Wm. H. Ulrich

In spite of the fact that a great many investigations have been carried out in recent years on the effect of ozone on air bacteria and odors and also on the physiological effects of ozone, the most diverse conclusions have been reached and opinions expressed with reference to the questions investigated. This confusion is due somewhat to faulty scientific technique and deductions from improperly chosen experiments as well as [illegible] point of view. The most recent criticisms against ozone in ventilation are found in two articles which were published in the issue of September 27th, 1914, of the *Journal of the American Medical Association*, one by Jordan and Carlson and the other by Sawyer, Beckwith and Skolfield on the bactericidal, physiologic and deodorizing action of ozone. A number of errors in the methods used in the experiments given in these articles have been noted and these seem so serious and the articles have been so widely quoted that it seems desirable to correct the misapprehensions which have been produced. Both of these articles refer to the fact that exaggerated claims were made by agents selling ozone machines.

In the article by Jordan and Carlson it is stated on page 10 that the concentration of ozone is determined by drawing the ozonized air through a solution of potassium iodide which has been acidified with sulfuric acid. The liberated iodine is then titrated with thiosulfate solution. It is well known among chemists that an acidified solution of potassium iodide is readily oxidized by the ordinary oxygen of the air and therefore if an acidified solution of potassium iodide is used for the determination of ozone the results will be high. The amount of the error will vary with the concentration of the ozone and may easily give results double the true concentration of ozone. This error can easily be demonstrated by drawing air free from ozone through such an acidified solution of potassium iodide. It is evident therefore that no reliance can be placed on the figures given for the concentrations of ozone which are reported in this article. In the article by Sawyer, Beckwith and Skolfield the concentrations of ozone were not determined.

It is universally recognized by ventilating engineers who are familiar with the use of ozone that it is of the greatest importance to regulate the concentration of the ozone and that ozone is useful only when employed in the proper concentration. This well known principle seems to have been so little understood by these investigators that they failed to make careful and accurate determinations of the concentrations of ozone used and therefore many of the conclusions which they reached are entirely vitiated.

Another very serious error in experimental procedure is found in the tests which were made on the effect of ozone on odorous substances. A considerable number of such substances were experimented with, and the conclusion was reached that the ozone *masks* these odors but does not destroy them and that therefore ozone is not useful in the removal of such odors.

The method of procedure consisted in exposing the substance giving off the odor until a marked odor was noticed in the small closed room which was used for the experiments. The ozone machine was then operated until a strong odor of ozone was produced. Observations were made from time to time of the odor in the room and it was observed in a good many cases that the ozone odor gradually disappeared and the odor of the substance experimented upon returned. In some cases ozone was again generated until its odor was pronounced and observations again made with reference to the disappearance of the ozone odor and the reappearance of the odor of the substance experimented upon. The conclusion was drawn that the ozone did not destroy the substance giving the odor but masked it. This conclusion was based upon the disappearance of the ozone odor and the return of the other odor. No other evidence whatever on this point is presented.

In these experiments no attempt seems to have been made to determine the amounts of the odorous substances which were present in the air except by the odor. The experimenters apparently did not consider the fact that the odors of substances differ a great deal in intensity, and that the quantities of substances which would be present, even though the intensity of the odor was the same, would differ very much. These authors also failed to keep in mind that the destruction of odors by ozone is an oxidizing process and that this, as well as all chemical reactions, is quantitative in the sense that a definite amount of oxygen is required to oxidize a definite amount of an oxidizable substance.

The following reaction takes place when ozone oxidizes hydrogen sulfide:

$$H_2S + O_3 = H_2O + S + O_2$$

That is, 34 parts of hydrogen sulfide would require 48 parts of ozone for their oxidation. When the hydrogen sulfide is dissolved in water the sulfur liberated is still further oxidized by the ozone to sulfuric acid, which would require a still larger quantity of ozone but according to the reaction given a somewhat larger amount of ozone than hydrogen sulfide would be necessary for the destruction of this substance. Now if the intensity of the ozone odor is much greater than that of the odor of hydrogen sulfide, the hydrogen sulfide would be oxidized by the ozone in the experiments reported by Jordan and Carlson and some other authors quoted, and the hydrogen sulfide odor would then return as reported by these investigators.

In order to verify these conclusions experiments were carried out to ascertain the amount of hydrogen sulfide which will give a distinct odor. A large balloon flask of 30 liters capacity was used. The hydrogen sulfide was produced by treating known weights of carefully analyzed iron sulfide with dilute sulfuric acid. The reacting substances were placed on a watch crystal suspended in the center of the balloon flask. In addition to the odor, tests were made with lead acetate paper.

INTENSITY OF ODOR OF HYDROGEN SULFIDE

Mg. H_2S per Cubic Meter	Test with Lead Acetate Paper	Odor
977	Very black	Very strong
244	Very black	Strong
61	Very black	Distinct
30	Turned black slowly	Fairly distinct
15	Brown on edges	Faint
7.6	Turned brown very slowly	No odor

While to obtain a distinct odor of hydrogen sulfide 61 parts are required the odor of ozone is very marked when present to the extent of one part per million, the limit being one-tenth part per million. In the experiments of Jordan and Carlson, the concentration of the hydrogen sulfide must have been from 30 to 60 milligramme. One part of ozone would have given a strong odor which could mask the odor of the hydrogen sulfide until by the oxidation of the latter the ozone was decomposed. Less than one part per million of the hydrogen sulfide would be destroyed by this oxidation leaving a sufficient amount of hydrogen sulfide to give a very distinct odor. On again generating ozone until a strong ozone odor was obtained, the hydrogen sulfide would be again masked and when the ozone odor had disappeared the hydrogen sulfide odor would reappear. This could be done repeatedly, as reported by Jordan and Carlson. The conclusion which they drew, however, is entirely unjustified, namely, that their experiments showed that the hydrogen sulfide odor was merely masked and hydrogen sulfide not oxidized or destroyed by the ozone.

In order to verify this conclusion, the following experiment was carried out. A concentration of 25 milligrammes of hydrogen sulfide was treated with ozone of a concentration of 35.6 milligrammes per liter. In these concentrations there would be just enough ozone to oxidize the hydrogen sulfide. In this experiment the ozone odor was at first very pronounced but after this odor had disappeared there was no hydrogen sulfide odor. A slight acidity was indicated by the reddening of blue litmus paper. The ozone used had been very carefully tested for nitrous oxides, but none was found.

Another experiment was carried out in which the ozone concentration was 7.6 parts per million, while the hydrogen sulfide concentration was 60.7 milligrammes per cubic meter, so that only a small part of the hydrogen sulfide could be oxidized by the ozone present. At first only the odor of the ozone could be detected. The hydrogen sulfide odor gradually returned so that within one hour a faint, and after two hours a distinct, hydrogen sulfide odor was detected, while the ozone odor had entirely disappeared.

This experiment could be repeated three or four times, as reported by Jordan and Carlson on page 33 of their article. They further state: "The mechanism of this masking action of ozone does not concern us here." If the authors had considered the "mechanism" of this action they might have reached entirely different conclusions and would have seen that their experiments were in exact accordance with the theory that ozone oxidizes hydrogen sulfide and other substances. They still further refer to the fatigue of the olfactory end-organs by the ozone. They say "Strong concentrations of ozone rapidly fatigue or anesthetize the olfactory epithelium". One wonders why the authors did not make this statement general, and state what every chemist has frequently observed, that hydrogen sulfide and the numerous other odors which are present in chemical laboratories produce the same effect on olfactory epithelium, so that these odors are not noticed by workers in the laboratory.

Hydrogen sulfide is also oxidized by the air, as is shown by the fact that the odor slowly disappeared in a duplicate experiment in the absence of ozone.

In some cases ozone acts as a catalytic agent. This was shown by the action of ozone on linseed oil. Weighed quantities of linseed oil were exposed to air and ozone. The oil exposed to air gained 17 milligrammes, while an equal quantity exposed to the action of ozone gained 110 milligrammes during the same time. The amount of ozone generated was 11.4 milligrammes. The ozone, therefore, acted as a catalytic agent, causing the absorption of 82 milligrammes of oxygen, which is nearly five times as much oxygen as was absorbed by the oil exposed to air alone. It is reasonable to suppose that ozone would act as a catalytic agent and cause the oxidation of other oils and organic substances similar to linseed oil.

In the case of ammonia the same considerations apply. Ammonia is oxidized by ozone in accordance with the following equation:

$$2NH_3 + 3O_3 = N_2 + 3H_2O + 3O_2$$

In this case, one part of ammonia is oxidized by about four parts of ozone. A study of the intensity of the odor of ammonia gave the following results:

INTENSITY OF THE ODOR OF AMMONIA

Mg. NH_3 per Cubic Meter	Test with Litmus Paper	Odor
1 000	Turns blue readily	Strong
659	Turns blue slowly	Fairly strong
329	Turns blue slowly	Fairly strong
165	Turns blue very slowly	Fairly strong
82	Turns blue very slowly	Quite distinct
41	Turns blue on edges very slowly	Faint
21	Turns partially blue on edges very slowly	Very faint
10	No action	No odor

Experiments were carried out in which known amounts of ammonia were treated with definite amounts of ozone and the ammonia remaining was determined by absorption with sulfuric acid and nesslerizing. Ammonia is acted upon very slowly so that 24 hours were allowed for the reaction. The concentration of the ozone was 35.6 milligrammes and of the ammonia 125 milligrammes per cubic meter. After 24 hours, 78 milligrammes of ammonia remained in the flask containing air and 75 milligrammes in the flask containing ozone. The quantity of ozone present was sufficient to oxidize 8½ milligrammes of ammonia per cubic meter. The experiment indicates some oxidation of ammonia by ozone. Erlandsen and Schwartz[1] state that their results showed no action of ozone on ammonia.

Experiments were also carried out to ascertain the intensity of the odor of oil of cloves. It was found that 66 milligrammes per cubic meter would give a strong odor. The amount of ozone necessary to oxidize oil of cloves cannot be calculated exactly, but it would probably require several times more than an equal weight. On subjecting the oil of cloves vapor in a concentration of 36.6 milligrammes per cubic meter to the action of ozone of a concentration of 32 milligrammes per cubic meter, it was found that at first a distinct odor of ozone could be detected, which gradually disappeared and was replaced by a sweet odor which had no resemblance to the strong odor of the oil of cloves. Very evidently the oil of cloves, or one of its strong smelling constituents, is oxidized, at least partially, so as to leave an organic compound having an entirely different odor. The flask was allowed to stand a total of 21 hours, although the reaction was practically complete within 2 to 3 hours. The reaction did not seem to be entirely regular. The experiment was repeated several times and the formation of the sweet aromatic substance repeatedly observed, but at times the odor of cloves persisted. Any excess of ozone was removed by shaking with 10 per cent ferrous sulfate solution. Control experiments were also made with a balloon flask containing oil of cloves and air only. Erlandsen and Schwartz have made a similar observation with respect to skatol and indol. They state that these substances are completely decomposed by ozone with the formation of pleasant smelling substances similar to [illegible]. They also state that mercaptan is rapidly decomposed by a large excess of ozone.

*Read at the 8th Semi annual Meeting of the American Institute of Chemical Engineers, Troy, New York.

[1] [illegible]

These authors also found that hydrogen sulfide is oxidized by ozone. Jordan and Carlson also mention the work of Erlandsen and Schwarte, but state that the results of the latter agree with those of Jordan and Carlson in showing that ozone *masks* odors and does not oxidize the substances discussed Jordan and Carlson even state that "The inability of ozone to oxidize (to any appreciable extent) ammonia vapor and oil of cloves is very striking" Franklin gives the results of experiments showing the oxidation of a great many organic substances, and demonstrated that carbon monoxide is oxidized to carbon dioxide [1]

Undoubtedly many of the conflicting conclusions which have been reached are due to the failure of experimenters to take into account the quantitative relations between ozone and the substances to be oxidized and have generally failed to realize that on account of the much greater intensity of the odor of ozone than that of other substances producing odor far too little ozone has been employed in the experiments The odor of ozone is at least 100 times as intense as that of other substances having a pronounced odor

The common method of using ozone to destroy odors seems to be justified by these considerations The ozone machines in good practice are operated so that a very small concentration of ozone in the air is produced The continued renewal of this small amount of ozone oxidizes the odorous substances and gives the total quantity of ozone required by chemical theory

Jordan and Carlson undertook to prove that ozone does not destroy smoke by coating a piece of glazed paper uniformly with a thin film of lampblack and subjecting the carbon to the action of ozone for 10 hours and state that there was no effect on the lampblack They regard this as evidence that ozone does not destroy smoke although they state that smoke also contains carbon monoxide sulfurous acid etc They seem to have made no attempt to study the effect of ozone on carbon monoxide and sulfurous acid, but state that the assertion that ozone destroys smoke is equivalent to a deliberate deception because ozone does not oxidize carbon particles suspended in the air Not being chemists, Jordan and Carlson might not have known that carbon is extremely difficult to oxidize, but they should have known that carbon monoxide and sulfurous acid, as well as creosote and other pungent and aromatic organic substances present in smoke, produce disagreeable and toxic physiological effects It is just these constituents of smoke which are easily oxidized by ozone The carbon which is not acted upon is totally inert and harmless

Jordan and Carlson also carried out investigations on the action of ozone on air bacteria. As has already been stated, their determination of the concentration of ozone cannot be relied upon because acidified solutions of potassium iodide were used which give high results The authors admit that the plate method which they used was not an exact one, and that therefore the results were irregular They obtained a reduction of bacteria from 64 to 38, 49 to 18, 61 to 67 (increase), 78 to 34, that is, the bacteria were reduced to 40 6 per cent, 63 3 per cent and 56 4 per cent in three tests while in the fourth there was an increase to 109 8 per cent Most authors would discard the fourth test and consider the reduction to be about 55 per cent Jordan and Carlson then tried Winslow's more exact method, but did not use a large enough sample for the test (4 5 liters), so that the highest number of bacteria counted was 7 It is not good practice in bacteriological work to rely on counts of so small a number Jordan and Carlson draw the following strange conclusion from their results

The alleged effect of ozone on the ordinary air bacteria, if it occurs at all, is slight and irregular even when amounts of ozone far beyond the limit of human physiological tolerance are employed '

There is no reason to suppose that the ozone used in these experiments was 'Far beyond the limit of human physiological tolerance ' The reduction in the number of air bacteria is not "slight and irregular" The experimental results of Jordan and Carlson agree with the results obtained by one of us[2] in New York school rooms showing a reduction in air bacteria and moulds of 75 per cent, 91 per cent and 91 per cent, the greater reduction resulting from longer exposure to ozone. No ill effects were observed on the children and adults present during these tests.

Jordan and Carlson (p 34) state "Some bacteria are undoubtedly killed by ozone, especially if they are in a moist condition." This statement is correct as it is generally recognized that ozone destroys moist bacteria very rapidly. The conclusion drawn by Jordan and Carlson is very far from being correct. They say "Incidentally, however, the fact is of very slight importance. The works of Chapin, Doty and of Winslow and [illegible] have fairly disproven the belief held so long that bacteria existed as a menace in rebreathed air It has been shown that infection occurs but rarely from air-borne bacteria and then only when the *bacteria are in the moist condition* It is just these virulent bacteria which are quickly destroyed by ozone even in low concentrations The bacteria which resist the ozone are powerless to transmit disease

It is by no means necessary to show that ozone is capable of sterilizing the air in order to show that it is useful in ventilation There is in fact no other disinfectant which can be used even in low concentrations in living rooms All other known disinfectants are highly dangerous in concentrations high enough to be at all effective Ozone in low concentrations will both remove odors and will materially reduce the bacteria content of the air

Jordan and Carlson attempted to show that ozone is dangerous by subjecting guinea pigs to high concentrations until the animals died They also forced strong ozone (10 parts per million) directly into the lungs of dogs and rabbits after performing tracheotomy under ether and inserting a tube well below the larynx and treating the wound with cocaine They say they did this because at least three-fourths of the ozone is decomposed by the mucous membrane of the respiratory passages It is difficult to see what bearing this experiment can have on the use of ozone in ventilation The ozone which was forced into the lungs must have been several hundred times as concentrated as it is ever used in ventilation It would have been quite as logical to place animals in pure oxygen or even an atmosphere of 50 per cent oxygen and also force these gases directly into the lungs When the animals died and the lungs were found to be inflamed the conclusion might be drawn by highly academic experimenters that it is dangerous to breathe air containing 20 per cent oxygen

Jordan and Carlson carried out experiments with what might be called low concentrations of ozone They subjected 4 cats, 4 rabbits, 6 guinea pigs and 12 rats to ozone of 1 part per million nine hours daily during two weeks so that irritation of the eyes and nose was produced Body weight, appetite and general condition were noted No ill effects on appetite and body weight or general condition could be observed The conclusion could, therefore, be drawn that ozone in moderate concentrations is harmless but Jordan and Carlson warn us that this conclusion is not justified

They say We desire to state, however that this test does not warrant the conclusion that the ozone in concentrations that may be used in practical ventilation is harmless to man Two weeks is a short time in the life of a man If ozone in ventilation should come into general use, it would mean in the case of office and shop workers exposure to ozone from 6 to 10 hours a day 6 days of the week, from 9 to 12 months of the year for from 20 to 50 years And even if this prolonged exposure to ozone should prove harmless to the robust person what about the unfortunate person whose lungs *have only slight power of resistance?*

Jordan and Carlson seem to have fallen into the error of assuming that because they have not tried to and therefore have not demonstrated actually, benefit from the use of ozone, this is equivalent to having demonstrated the reverse, i e, the harmfulness of ozone

If the facts presented in this paper are properly interpreted they will be found to be in accordance with the view that ozone is a powerful disinfectant and deodorizing substance which, in suitable concentration is without any injurious effects whatever The elimination of odor is by no means the least important function of ozone and there is no other agency available except dilution with fresh air In many cases it is impossible to introduce enough air for this purpose without producing annoyance and dangerous drafts of air not to mention expense of blower installation and operation as well as heating the air As a matter of fact before ozone was available, disagreeable odors have often been considered unavoidable nuisances which could not be eliminated or overcome.

With reference to the alleged harmful effects of ozone, no single instance of harm to a person from the proper use of ozone in ventilation has been published, but all adverse opinions have been deduced, by inference, as in the paper by Jordan and Carlson, from experiments performed with very high concentrations, while all efforts to produce harm experimentally with weak ozone have failed.

Jordan and Carlson report that 26 animals, exposed for 14 days, during 9 hours each day, to concentrations high enough to cause irritation of the eyes and nose, suffered no ill effect whatever Hill cites the cases of the numerous workers in the London underground tubes who have shown no ill effect in three years. Gmunder cites the tubercular workers in the spinning mills at Reutlingen, and numerous similar instances of prolonged proper use of ozone without a single complaint are to-day in existence. The Jordan and Carlson report is the most elaborate and convincing laboratory test that has been published.

Report of the Bureau of Mines

THE annual report of the United States Bureau of Mines issued by the director Joseph A. Holmes discloses a surprising amount of useful work accomplished and clearly indicates the inestimable value this bureau could be to the country if sufficient funds were available to enable it to carry out the work that is clearly necessary

Broadly the lines of work of the greatest national concern devolving on this bureau are the safeguarding of the lives of miners and of the employees in the metallurgical and mineral industries and the development of a more efficient and less wasteful preparation and use of our mineral resources and while the latter of these is of vast monetary concern it is the former that will appeal most strongly to popular interest One of the first directions in which this work was prosecuted was in relation to safety in coal mines and a large number of details have been investigated with good results Among these are the studies that have been made as to the causes of explosions and their prevention the use of explosives and electricity in mines ventilation and rescue work as well as many other points In the mine rescue work six mine rescue stations have been established as well as eight rescue cars and one motor truck all of which have rendered most valuable aid in cases of accidents and the bureau itself has been directly responsible for the saving of a number of lives One of the most valuable and permanently useful branches of this work has been the instruction given to miners and during the year 2840 miners were trained in rescue work and 5780 were trained in first aid methods At the end of the year 24 975 men had been instructed altogether and through their means a knowledge of rescue work is spreading rapidly Other investigations looking to making mines safer are under way but much more could be done if greater resources were available

The importance of the work that can be done in the prevention of waste may be understood from the statement that the total wastes or losses in mining and utilizing our mineral resources now amount to more than $1 000 000 a day and when it is realized that these losses are irreplaceable the desirability of prompt action is apparent That the bureau is doing splendid work in this direction is shown in a single item for by the expenditure of less than $15 000 a saving of natural gas has been made of not less than $1 500 000 or more than the bureau has cost since it was organized

A careful estimate indicates that in the mining of 600 000 000 tons of coal during the last calendar year there was wasted or was left underground in unminable condition 200 000 000 tons of coal and it is believed that more than half of this loss is preventable Of petroleum not less than $10 000 000 in value is annually wasted by present methods In the ordinary process of coking coal $75 000 000 is lost annually These are but indications of the work that should be done and the directions in which the bureau is employing its activity and there are multitudes of others requiring attention *One interesting study undertaken by the bureau was in* regard to radium uranium and vanadium with a view to developing methods for the cheaper extracting of these valuable metals from their ores both with a view to reducing the price and to develop the radium industry in this country and stop the exportation of our ores to foreign countries where they are now treated As a result of this study which was undertaken in connection with the National Radium Institute methods for the extraction and purification of radium vanadium and uranium from carnotite ore have been devised The methods have given satisfactory results and indicate radium can be produced at a much lower price than that at which it is sold at present.

While in some quarters the narrow view is taken that anything that assists mining or metallurgy in this country will be only for the advantage of some corporations the reading of this report is convincing that the field covered by the Bureau of Mines is to the direct advantage of every citizen of this country no matter who may benefit incidentally for it is the public that pays eventually for every waste, and the cheaper and more economical production can be made in any direction the lower will be the price at which the goods can and must be sold and it is becoming more evident every day that no time should be lost by the Government in extending to our mineral industries and manufactures the aid that is so liberally given to many other departments that are conducting valuable investigations of our resources. Incidentally it may be remarked that the policy of withholding aid from the mining interests for fear it may assist some corporation is likely to be the surest way to create monopolies, for the small mine owner cannot afford to develop economical processes that will enable him to compete with the big concerns, and if the Government does not help him in this way his only resource is to transfer his property to the large corporations.

The Diary of Kilauea*

Volcanic Action in Hawaii Being Observed and Recorded

An important contribution to scientific knowledge is that just published by the Society of Arts. The Institute has recognized the need of systematic observation of volcanoes and for this purpose has established in the Hawaiian Islands an observatory where with most recent methods and equipment the facts that the crater has to offer are to be collected. The work owes its initiative to the interest and activity of Prof. T. A. Jaggar, Jr., of the Geological Department, who is the director of the Hawaiian Volcano Observatory.

The report of the Hawaiian Volcano Observatory is a neat quarto of seventy-five pages, well illustrated, which gives the history of the institution and its work up to and including 1912.

Crater of Halemaumau, about January 4th, 1912

In 1912 the observatory was put on a five year foundation and early in the year the present building was constructed. Dr. Jaggar was named head of the observatory and relieved of his duties in Boston for the purpose of making investigations at the volcano of Kilauea, where the station is located.

The institute has the lease of a tract of three acres on the brink of the crater, with the option of renewal, and its station includes living rooms, administration offices and work rooms, while the Whitney Laboratory of Seismology is a basement room of concrete, floored on the solid ledge of basalt. The place of the instrument house is most striking, being on the very edge of the rim, where at times the clouds from the crater encompass it. During some of the experiments it has been necessary to establish a line of assistants who by calls from one to another directed the manipulation of the instruments.

The story given in the report is largely a day by day account and valuable for scientific purposes. The conduct of the fiery lakes in the bottom of the crater is chronicled, the oscillations of the lakes within their basins, the different kinds of action, the fountains, one of which, "old faithful" was playing at intervals of thirty seconds sending fiery spray to one hundred feet in height, while the earthquake shocks of every little while are noted.

Experiments were made in gas-composition of the vapor clouds above the lakes, the flows of molten lava into fiery pools are described and the floating island. New cones on the floor of the great crater are a phenomenon of interest, the fall of the crater walls, the range of the fire with reference to surface, are features in an activity that knows no cessation.

Part of the work was that of Perret and Shepard, the former the well known vulcanologist and the latter detailed for the work by the Carnegie Institution. In this series of observations a cable was stretched across the lake and from it the thermometers were lowered into the lava to ascertain its temperature. It was a very difficult performance and one after another of the instruments were lost on account of the heat and acid condition of the vapors, which melted or corroded the wire ropes. One record was obtained, however, at 1,900 deg. Fahr., and a moment after the wire ropes were melted and the instrument lost. It was the third pyrometer thus to be destroyed, but the observation is considered to be a good one of the temperature of Kilauea lava.

One of the striking matters presented by this volume is a bit of prophecy. Dr. Jaggar thinks that there is a rhythmic escape of lava which has been fairly well verified by the records of past eruptions. Mauna Loa, which is the subject of this prediction, seems to have decreased the duration of its eruptive periods, which previous to 1868 were eleven and one half years long and since that date have been five years long. The time between these periods when the volcano has remained quiet has decreased from five and one half years to four and three quarters. Applying these figures to the last eruption Dr. Jaggar is looking for renewed activity in this volcano in February, 1915. There is really no satisfactory information on which to predict the month, but from the usual conduct of the volcano February seems the most probable. It will be of great interest to know whether this prediction, made in September, 1912, is fully realized.

Food for Polar Explorers

In a recent article in the *Daily Telegraph*, London, Sir Ernest Shackleton discusses the important question of food supplies and the proper diet for explorers in polar regions, and as these are questions of vital importance in regions where temperatures not far short of 80 degrees below zero are common, as the success of such expeditions depends primarily on the health of the explorers, this article is quoted in full and will be found of general interest, particularly the tables giving the scale of food rations that has been prepared by Colonel Beveridge, of the Royal Army Medical College, particularly for this expedition.

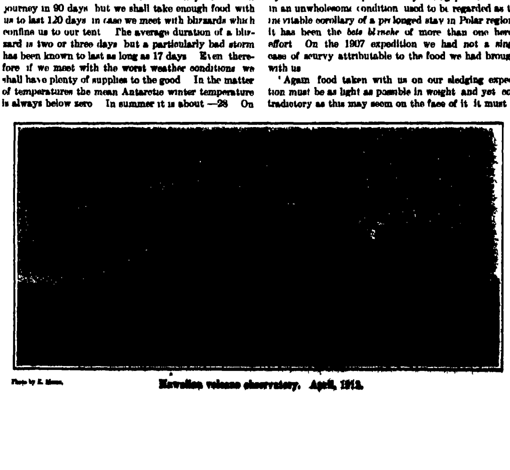
To provide the best kind of nourishment under the long and, even at their best, somewhat trying conditions of the Polar regions is a matter of considerable thought and anxiety in the organization of such an expedition as ours. Captain Scott, whose great achievement and tragic death are ever fresh in mind, gave the matter his most careful consideration. But I believe this is the first occasion when Polar explorers will have the benefit not only of practical experience, but of scientific experiments and tests which should prove of very great advantage in the coming effort.

The sledging distance to be covered will be roughly 1,800 miles, and the first half of this, from the Weddell Sea to the Pole, will be over unknown ground. Every step will be an advance in geographical science. It will be learned whether the great Victoria chain of mountains, which has been traced from Ross Sea to the Pole, extends across the continent and thus links up (except for the ocean break) with the Andes of South America, and whether the great plateau around the Pole dips gradually to the Weddell Sea. Continuous magnetic observations will be taken on the journey. The route will lead to the Magnetic Pole, and the determination of the dip of the magnetic needle will be of importance in practical magnetism. The meteorological conditions will be carefully noted, and this should help to solve many of our weather problems. The glaciologist and geologist will study ice formations and the nature of the mountains, and his report should prove of great scientific interest. This, apart from the scientific work of the base parties, one of whom I shall leave on the Weddell Sea and the other of whom I hope to meet on the Ross Sea at the conclusion of my long march.

On this march, which is roughly 1,800 miles, I shall have the company of Mr. Frank Wild, my second in command, who served with distinction during an extended sledge journey during the National Antarctic Expedition, 1901-4, and who was one of the southern party of my last expedition (1907-9), together with four picked men. Given favorable conditions we hope to do the journey in 90 days, but we shall take enough food with us to last 120 days, in case we meet with blizzards which confine us to our tent. The average duration of a blizzard is two or three days, but a particularly bad storm has been known to last as long as 17 days. Even therefore, if we meet with the worst weather conditions we shall have plenty of supplies to the good. In the matter of temperatures the mean Antarctic winter temperature is always below zero. In summer it is about —28. On the plateau it is 40 degrees below zero, but in the spring months the temperature falls as low as 75 below zero.

Now several important considerations have to be borne in mind in selecting food supplies for conditions such as these. The food must be wholesome—it must be uncontaminated—and nourishing in the highest degree. Only by the most nutritious and (as far as possible) most varied food can one hope to hold the dread disease of scurvy at bay. There was a time when scurvy, which is often produced by eating preserved food in an unwholesome condition, used to be regarded as the inevitable corollary of a prolonged stay in Polar regions. It has been the *bete blanche* of more than one heroic effort. On the 1907 expedition we had not a single case of scurvy attributable to the food we had brought with us.

"Again, food taken with us on our sledging expedition must be as light as possible in weight, and yet contradictory as this may seem on the face of it, it must be



Hawaiian volcano observatory, April, 1912.

substantial. Excessive concentration not only diminishes its nutritive value almost to nil but renders it less easy of assimilation. Bulk is as essential as nutritive value. In very low temperatures the heat of the body which is the life of the body can be maintained only by use of fatty and farinaceous foods in such liberal quantities as circumstances allow. Then again sledging food supplies must not require much cooking. Something that can be heated easily and quickly is the desideratum for the amount of fuel that can be carried is strictly limited and if it runs out there are no means of replenishing it. Failing the means of heating the food it must be of a character that can be eaten without cooking at all. In winter quarters at the base camps—a great variety of food is possible.

"On our sledging journey to which I have already referred our rations will be 35 ounces per man per day containing 5 512 calories. In normal life an ordinary man eats about 3 pounds of food a day containing some 2 500 calories so that we shall have the benefit under Polar conditions of some 3 000 calories per man.

Here are the sledging rations in total we are taking with us, calculated to last for 20 men for 100 days per man.

	Lbs
Unhulled Scotch oatmeal fine ground	500
Lard (pure)	1 000
Sugar (ground centrifugal)	150
Sugar (loaf)	300
Beef powder	375
Glidine	125
Biscuits (Antarctic, H and P)	875
Trumilk	300
Nut food (6 ounce packets)	750
Lime juice (concentrated, made into lozenges or capsules)	65
Cerebos salt (in packets containing 0 75 ounce)	16
Meat extract (in 5 ounce cubes)	65
Tea	32
Total	4,553

"The whole of it is being packed in oblong boxes of 60 pounds each (oblong because it is easier to handle and balance this shape). The boxes are made of Venesta wood, which is both light and durable. Everything in the nature of meat is in skins which come in useful for feeding the dogs although if necessary we shall eat the skins ourselves. I hope it won't be! These rations are going out in a refrigerator and will remain in refrigeration until they arrive at their (first) destination in the land of the Southern Cross. Among the articles mentioned in the tables given herewith the lime juice has been concentrated down at a temperature of not more than 95 deg. Fahr. so that the anti scorbutic properties are thereby preserved. Glidine is a vegetable protein while Trumilk has this advantage over ordinary dried milk that it has not been subjected to a heat so great that the vitamines are thereby destroyed.

It will be seen that we are to have a total of 11½ ounces for breakfast. While in Norway recently we found that we could not eat two-thirds of that for our matutinal meal and I fancy there are few men in England even among the laboring classes who are subjected to strenuous work who could manage as much for the morning meal.

Our only stimulant will be tea. We shall have a small quantity of brandy with us but only for medicinal use in emergency. It often happens that in uplifting the arms to fix the tent for sleep the blood rushes from the hands and the fingers become instantaneously frost bitten. A man is then quite *hors de combat* but a drop of brandy will help to give a fillip to the blood in the affected parts.

In the ordinary way breakfast is taken at 6 A. M. luncheon at noon and supper at 6 P. M. But to achieve the object of our sledging journey we—I mean myself Wild and our four comrades—propose to split up the 24 hours into a 19 hours day. That will give us 8 hours marching, 8 hours sleep and 3 hours for the preparation and taking of meals. As far as possible our days and nights will be arbitrarily fixed in this fashion but our speed necessarily depends upon a variety of circumstances.

"Our last supply of fresh meat and vegetables will be taken on board at the Falklands. It may be possible to carry enough to last us a fortnight. After that we shall take to our special supplies.

"We are also taking some soil and seeds and hope to grow just a small quantity of oats, barley, rape, mustard and cress and peas. As the green shoots come up they will be cut and made into sandwiches. We may be able to take a few of these sandwiches with us for a very special treat on our 1 800-mile tramp.

The valuable tables of the sledging rations worked out by Colonel Beveridge are as follows:

SCALE OF RATIONS

Article and Amount	Moisture	Mineral matter	Protein	Fat	Carbohydrates	Calories
BREAKFAST						
Oatmeal 3 oz	4 03	0 88	12 04	5 44	31 02	[illegible]

The Largest Centrifugal Pump

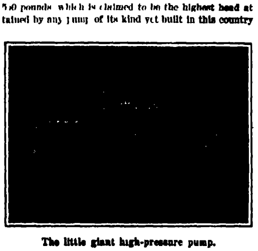
Modern engineering enterprises are wherever possible conducted on a gigantic scale for it has been found here as in business that doing things by wholesale is cheaper than retail methods. A recent case illustrating this occurred in New Orleans where very large quantities of water had to be handled in drainage work and to meet the requirements four immense centrifugal pumps were ordered which are said to be the largest of their kind in the world.

These big pumps have a delivery opening of 78 inches diameter and are capable of delivering 168 000 gallons of water per minute at a one foot head which is equal to the flow of a good sized stream. The head of water will vary under different working conditions from one to thirteen feet and at this latter difference of level 90 000 gallons per minute can be handled but the pumps are required to turn up much faster than at low lifts for whereas they do their work at 55 revolutions per minute when the head is but one foot, it requires 113 revolutions to move the stated amount at the 13 foot head. This however is by no means excessive and the pumps will be very economically operated by Nordberg Corliss compound condensing engines.

Besides these monsters there will be a fifth pump in the outfit which has an outlet of 48 inches and a capacity of 47 500 gallons per minute at 3 foot head as against 156 000 gallons at the corresponding lift by its big brothers. These pumps are built by the South Wark Foundry and Machine Company of Philadelphia.

A picture of one of the big 78-inch pumps as it appeared in the erecting shops of its builders is shown in the cover illustration of this issue and some impression of its unusual proportions can be obtained by comparison with the figure of the man who stands in the outlet opening.

As a contrast to these huge monsters a small high pressure three-stage turbine pump by the same makers is also illustrated and this is a little giant in its own way. The outlet of this small pump is but 6 inches in diameter but when running at 1400 revolutions it delivers 750 gallons of water per minute under a head of 530 pounds which is claimed to be the highest head attained by any pump of its kind yet built in this country.



The little giant high-pressure pump.

Maps and Map Making*

An Historical Review of the Development of the Art of Topography

By Sir Thomas H. Holdich

A SAVAGE often possesses the instinct of rudimentary map making, that is to say, he has the fundamental instinct in him which certain animals (I might say all wild animals) have for direction. I remember once searching for an old and disused salt cave on the Persian coast which was said to be inhabited by devils and other unpleasant inhabitants, and which possessed extraordinary subterranean scenery of great wonder and beauty. It was a very hot and a very weary quest. We should, I think, have abandoned the search among the low hills which crowded down to the shore line, but that we observed a ragged and scantily clothed individual sitting in solitude on the shore with a suspicious lump of something before him which he was guarding carefully. The practised eye of my companion observed a native craft on the blue horizon which he rightly conjectured to be engaged in illicit salt traffic, and we at once found a way out of our trouble. The man on the shore could speak no sort of dialect that either of us knew, and we could only point helplessly to the lump of salt and to the hills, and insinuate by means of certain coins that we were not there to interfere with him; we only wanted to see where that salt came from. So with his fingers he drew a map on the sand, and he did it so well that half an hour's climbing led us into the narrow mouth of the cave, and we saw there what I believe no other European had ever seen.

The point of the story lies in the fact that precisely the same symbolism, the alphabet of map-making, came as naturally to the hand of that smuggler as it has to the hand of all map makers since the days of Ptolemy till now. The very earliest maps of which there is any record are those of Claudius Ptolemaeus, which were made about 100 to 150 A. D., but the earliest copies of them to which we can refer did not exist till about the year 1400, thirteen centuries after they were actually compiled.

But there were other maps during the thirteen centuries which elapsed between the making and the publishing of Ptolemy's maps, and some of them are remarkably interesting. St. Jerome's translation of the Greek work "Onomasticon," A. D. 388, deals with Biblical countries. A famous map of the world was compiled by a Spanish monk, St. Beatus, in A. D. 776. This makes the earth square, plants the Garden of Eden at the top of the map (which is the eastern side of it), with Eve and the serpent in orthodox relationship. The next important map is the "Cotton" or Anglo-Saxon map of the world, dating from about the end of the tenth century. Here Jerusalem is no longer the center, and Taprobana, or Ceylon, is at the top. A map dating from 1200 again places Jerusalem in the center, but from the Garden of Eden at the top there flow out five rivers, the Ganges being included. This is a diminutive map designed to illustrate a psalter, but room is found in it for a great variety of human monstrosities such as are common to all mediaeval maps. These remarkable additions to mediaeval mapping are really interesting as indications of the nature of the ethnographical knowledge of the time. It is quite probable that they represent the prevailing ideas of the educated, i. e., of the priestly class, regarding the strange living world beyond their immediate ken. About the year 1350, and for a century later, there was a popular history in England written by a monk at Chester, called the "Polychronicon," and in it there are two maps compiled in the conventional style of the day, full of Biblical legends and popular myths.

Coupled with much information of ethnological interest about men with one eye or with hairy bodies, we find these curious facts stated for the enlightenment of posterity: Germany, it is said, has a greater population than it is able to feed, while Ireland is both larger and wider than England. It seeks liberty, but *shirks work*. One of the latest of the mediaeval manuscript maps in the British Museum is a copy of a map compiled in 1460 by Fra Mauro. Its geography, says Mr. Villiers, shows an immense improvement on the last map of 1350, Europe being especially good.

Of the earliest printed maps just one or two require a short reference. There is the map known as the "Cusa" map, compiled before 1464, which is printed from a copper plate by Cardinal Nicolas of Kuesen, which was the chief map of its time, and a map of the world in the *Insularium Illustratum* of Henricus Martellus Germanus is to be noted as the first showing Portuguese discoveries. At this point in map history commences the first rudiments of modern cartography. A Dutch printed map by Johannes Ruysch first represents India as a peninsula. That was in 1507, and it indicates the gradual progress of geographical knowledge. The Waldseemuller map of about the same date introduces the New World and further defines Portuguese discoveries, and yet another Dutch map (for the Dutch may claim to be pioneers in this branch of the art of printing), usually known as Jan Seversen's map, which undoubtedly is much indebted to the Waldseemuller map for its material, is quite a good example of early topographical art. The mountains now assume the appearance of lines of haycocks, and the trees indicating forests are all of the pointed Noah's Ark variety. Strange beasts, including an enormous elephant, stray over the continents, and monsters of the deep indicate the perils of the sea. Thenceforward the gradual evolution of the printed map passed into the hands of Italians, who took a much stronger lead in geographical illustration than in geographical discovery. Gerard Mercator at the end of the sixteenth century was the great map maker of his day, and his projection (notable perhaps, for its simplicity) is in use at the present time. Mercator gives us by far the best map of Ireland yet produced.

It is to be regretted that the greatest geographers of the mediaeval ages (the Arabs) have left so little in the shape of cartographical illustration behind them.

There is no doubt a feature common to all these old-world maps which cannot be admitted now, but the old world endeavor to unite ethnographical knowledge to that of more prosaic geography is no longer considered admissible. In fact, it is the extraordinary wealth of an infinite variety of information conveyed by legend and by pictorial illustration which renders the old form of mapping so interesting and so confusing. There are indeed certain details which may be considered as historically useful. We learn something of what our forefathers knew about the world they lived in. We learn what their shipping was like, even if we cannot admit their sea-born monstrosities. We have found that in some details of geographical information they possessed a knowledge of facts which have been discarded since their time, only to be revived again as correct in modern days, as, for instance, in the case of the Nile sources and the mountains of Central Africa.

With the gradual evolution of a system of cartography which should first of all divide land spaces from water by outlining the continents and islands of the globe, and thereafter separate mountain systems from plains and secure some representation of the hydrography of the earth by delineating the course of a great rivers, there arose the imperative necessity for a form of projection of the map, the definition of parallels of latitude and meridians of longitude, by means of which *the true relationship of separate areas of the earth* could be correctly maintained. Obviously this necessitated careful measurement of the earth's surface in order to determine its figure and to establish laws and formulae whereby these parallels and meridians could be laid down accurately previous to the introduction of topography. Thus arose the science of geodesy, or earth measurement.

It cannot be too strongly insisted on that all sound map making must be based on sound geodetic measurement in the first instance. To put it shortly, Triangulation, which is the outcome of geodesy, is called upon to supply the framework or skeleton onto which the topograph or the body of the map has to be filled. This framework is furnished with a projected graticule system (i. e. with lines of latitude and longitude correctly defined) so that the picture or plan of the country in question can be carefully adjusted by means of the points fixed by the triangulation which are, of course, common to both the geodetic projection and the topographical map. This adjustment is the work of the cartographer. Sometimes, as in India, the cartographer and the actual topographical surveyor in the field are one and the same person. Sometimes, as in Russia, a highly practised cartographical artist is employed to take the field sheets from the hand of the topographer and translate them to the finished map without reference to the surveyor at all. It is this latter method, doubtless, which produces the most artistic effects, but it should be remembered that topography is not only an art but a twofold art. There is the cartographic art of translating the field map to the final sheet for publication, and there is the art, only really given to few, of representing Nature on the field-map as she actually exists. The art of the topographer thus combines that of the painter and the engraver.

I need hardly say that when I talk of making map pictures from Nature I am talking of the plane-table method of making them. It is the one process which fully deserves the appellation of art, and the beauty and advantage of this system of map-making is that it appeals to the highest artistic instincts. I do not mean that an inartistic effort may be inaccurate or useless.

If accuracy is our object, then no professional cartographer, however gifted with artistic imagination and draftsman's skill, can take the place of the man who sees and knows, into whose eyes the picture of great world-spaces has entered. Unfortunately, gifts of imagination combined with draftsman's skill often make very pretty showing. Experience will enable a clever cartographer, a draftsman who has never been in the field, to represent even complicated topographical features of an imaginary character with a skill such that even an experienced surveyor can hardly detect the lies in it, and so it comes about that if a map is to be judged by its accuracy and faithfulness to Nature, apart from artistic effect, it is very often the most unattractive maps that are the best. Please remember this, and remember also that the processes of reproduction vary infinitely, and that when you look at a really beautiful production full of harmonious light and shade and delicate indications of graceful features where effect requires them, and exclaim "What a lovely map! you may be merely the innocent victim of a skilful cartographer who has been backed up and perfected by a first-rate publisher.

It is interesting to observe the slow but gradual development of the art of topography from the earliest maps until now. The alphabet of the process has remained much the same. Mountains and plains, rivers and coast lines have been simplified and perfected so as to produce the most readable map, but the alphabet has not fundamentally altered. It is in the matter of relief chiefly that the change is noticeable. The earliest attempts at depicting mountains by pictorial elevation have given place to plan. The little groups of conical excrescences like bands of haycocks, were by no means unintelligible though purely conventional. Indeed, it may be doubted whether to some intelligences they are not even now a more effective illustration of hilly country than our latest and most scientific system of contouring. Between the two we may find every variety of method employed which can produce the effect required. In large scale maps dealing with comparatively small areas and involving no great differentiation in altitude it has long been decided that the only scientific method of depicting the country is by lines of contours (i. e. line of equal level) at definite vertical intervals. It undoubtedly has its drawbacks. There may even be a difficulty here and there in the distinguishing between an elevation or a depression unless the value of the contours above the datum are distinctly stated in figures. But it is beyond dispute that for all military or fiscal purposes the contoured map is the only one admissible.

Difficulties arise when the elevations on the face of the map rise from the status of hills to that of mountains, and with the gradual steepening of slopes the delineation of contours gets closer and closer until it is impossible to introduce them on small scale maps without overlap and confusion. This applies to the many forms of geographical maps from the scale of one inch to the mile downward, when it usually happens that some more artificial and less conventional method of illustrating mountains in plan is necessary. The difficulty is usually met by "hachuring," that is to say, by introducing broken instead of continuous contours, and abandoning regularity of vertical interval. It is here that the artist steps in.

The weakest link in that chain of processes which is the basis of scientific map-making lies in the process of combining new work with old. People ignorant of the processes of map-making can have little idea how much the process of revision enters into the matter. The rapidity with which fresh artificial topography, in the shape of roads, railways, [illegible], springs into existence, combined with the action of wind and weather in changing the face of Nature, keeps all the resources of the Ordnance Survey busy to keep pace with it. And it is almost impossible to maintain a high standard of up-to-date mapping, which is [illegible] in any one map [illegible] of any [illegible], [illegible] it. But when we come to the [illegible] of [illegible]

* Extracts from inaugural address before the Royal Society of Arts.

we include under the term geographical, i e, wide areas depicted topographically on small scales within the rigid lines of a restricted sheet, these variations in quality of accuracy become far more pronounced and more important. No one but the compiler (who keeps the record) can possibly say what is the exact value of any one portion of the map, how far it is to be trusted in the business of conducting military affairs or the international arrangement of boundary settlements

A naive belief in the accuracy of a printed map compilation has foundered many a high political programme, even when the geographical features which may form the basis for a treaty have already been correctly shown as they existed at the time the map was made. The face of the earth changes and locally changes very fast.

No need to elaborate this propensity of our earth world to change its face or of its more primitive inhabitants to change their habitations and call them perpetually by new names I only refer to it as a caution to map critics.

I have said a word or two indicating that the gift of imagination must still have its place in map making This may sound almost immoral although it is but a page from past records, and yet I have come to the conclusion that if the public is asked to exercise imagination in reading the map the map-maker must meet the public half way It is still, of course in the domain of geographical mapping where the conformation of the ground is partly well known partly indifferently known that imagination must here and there be called upon to supplement actual knowledge If the map-maker were to confine himself to absolutely what he knew to be true in the delineation of mountain and valley or of rough desert areas wherein no living creature moved he would simply leave large white blanks in his map which might in themselves be most misleading

It used to be the fashion to leave such blanks but in my opinion it is better to introduce mountains or deserts where they are known to exist to indicate all that can be seen from a distance than to make no sign at all The part of the map which is conjectural should of course be carefully indicated but there is doubtless a tendency on the part of enthusiastic explorers to consider much of these conjectures as certainty and to make no specific distinctions between what they know and what they think they know In this way it often happens that succeeding explorers in the same region are apt to condemn the work of their predecessors from want of knowledge of the exact nature of the different parts of that work

I may say just a word here about map criticism It is a most common thing for even intelligent travelers passing over a country with a map in their hands to report that they found the map all wrong Now in the case of expeditions into partially known lands it is only the expert who can say whether the criticism is a just one or not It most cases it is not for the simple reason that ordinary travelers have no means of identifying their position and do not know exactly where they stand while as regards place names although they may succeed in identifying the position named they are at the mercy of native guides and interpreters for their own information

There is one matter about which experts disagree more or less and it is one on which I think the public might well express an opinion It is the fashion now to indicate successive planes of elevation by flat tint and the ordinary application of color for that purpose is in shades of green for the lower elevations rising into brown which deepens with the altitude So well known is this system that I think it may be considered to have established a fair claim to permanence so far as British maps are concerned For my own part I can imagine nothing better for ordinary touring maps But difficulty arises when the altitudes are great rising to many thousands of feet as in mountainous regions Here it is admitted that no one universal system of color printing is satisfactory This is not an unimportant matter for it directly affects geographical education which now is so largely assisted in schools by wall maps In the effective preparation of these we want the opinion of both teachers and of artists

Astronomy in the Arctic*

Some of the Duties and Hardships of Observers in the Frigid North

By Russell W Porter

Some twenty years ago it was the fortune of the writer—or misfortune, rather—to become inoculated with the virus of that strange "wanderlust" known as the "Arctic fever" Since that time he has taken ten voyages above the circle The following notes on the part of his labors bearing on the astronomical problems arising in the extreme North may be of interest to amateur observers who have never strayed so far afield

The duties of the astronomer of a polar expedition are the determinations of the latitude and longitude of the winter quarters and Greenwich time There are other activities, such as the mapping of any new lands observations in connection with magnetic work etc but the first-mentioned are the most important, particularly a knowledge of the Greenwich time—for, as we all know, the meridians of longitude converge at the Pole to a point, and the longitude is the difference between local and Greenwich time Therefore it is quite necessary that a person traveling toward the Pole over a shifting sea of ice should know upon what meridian he is journeying, and that on his return from the Pole he should know upon which of the meridians he is descending, in order to arrive safely at his base of supplies The compass due to its weak horizontal component is too unreliable a guide

The Greenwich time is transported from civilization to the winter quarters by means of chronometers on the ship. Were their rate of gain or loss uniform this method would be sufficient But the shock of the ship in forcing a passage through the ice is very great and the clocks change their rates, so that, arriving at winter quarters after a summer's battering through ice floes, a knowledge of the time at Greenwich is very poor and not to be depended on So recourse is had to other and absolute methods—either by occultations of stars by the moon, or moon star culminations From either of these observations the center of the moon is determined in right ascension at a certain instant of local time and by entering an almanac and finding what the Greenwich time is when the moon has this right ascension and by taking the difference between these two times the longitude is at once obtained The degree of accuracy so found is not great, but it must be remembered that a degree of longitude near the pole is a very much smaller quantity than at the equator, so that, for practical purposes, quite a large error is admissible

On the writer's last Polar expedition, an observatory was erected on a basalt ledge one hundred yards from the house. It was about 7 feet square, with walls of matched sheathing, north and south shutters, and a shutter in the flat and slightly inclined roof A transit instrument by [illegible] with 12-inch circles reading to single seconds of arc was set up on a brick pier The chronometers at the house were never disturbed Beats from the sidereal break-circuit clock were heard by means of a sounder on the wall of the observatory A collimating pier a few feet north of the transit served for the north meridian mark while a signal made of several biscuit tins one on another placed on a glacier a few miles away, served as a south meridian mark By swinging the instrument out of the meridian and sighting through a hole in the wall the magnetometer of the magnetic observatory some thousand feet away could be seen and thus all magnetic declinations referred to the primary meridian

The writer spent many long hours in the observatory through the winter night with his eye to the telescope watching the tiny star disks passing across the seven vertical threads of the reticule Dressed in heavy furs with one hand bare to record the time intervals he was obliged to sit motionless for sometimes two or three hours at temperatures ranging from 30 degrees to 60 degrees below zero with no artificial heat and the bitter wind passing freely through the building At times the room would suddenly fill with a fog so thick as to require an immediate cessation of work Often the oil in the illuminating lamp hardened to the consistency of slush and the lamp refused to burn Tiny ice particles of hoar frost were very bothersome settling on the pivots of the transit and throwing the horizontal axis out of level There was no running around the block stamping the feet, or swinging the arms to restore circulation—just a steady nerve-racking watch

Those observing at the magnetic hut fared no better Here the vagaries of the needle were watched and recorded every two minutes over an unbroken interval of nearly two years

The peculiar conditions surrounding the pole present other obstacles The sun never mounting high in the heavens is weak in actinic rays hence the photographer has his troubles In using an artificial horizon with a sextant the small angle of incidence prevents the whole disk of the sun from being observed In fact the small transit instrument is altogether preferable to the sextant in polar work Those made especially for the Ziegler polar expedition were but little heavier than the sextant and mercury basin and far more useful

During the long summer's day of four months the writer has tried to find the moon but has never succeeded The heavens are not blue but a bright, glaring grey due to the reflection of the sunlight from the surface of the snow It very effectually "puts the moon out of business," as far as the astronomer is concerned On the other hand, in the winter night the moon is above the horizon continually through half of each lunation, and has much the same appearance as in lower latitudes.

Imagine yourself at the pole, with the meridians of longitude radiating out from your feet until they disappear over the rim of the horizon It is about June 21st, the summer solstice, and the sun is revolving around the heavens at an altitude of some 23 degrees, as ever just once in twenty four hours but neither rising nor descending in its path through the sky What time is it for you as you stand there—that is time as understood by an astronomer? The answer is easy there is no local time It is equally true to say that it is all hours Now step off the pole toward the sun wherever it may happen to be You are now on the meridian over which the sun is situated It is noon to you astronomical noon Take two steps backward you have crossed the pole are on the same meridian and it is astronomical midnight In this manner you can make the time of day anything you choose by simply taking one step away from the pole in the direction of the meridian on which that particular time obtains

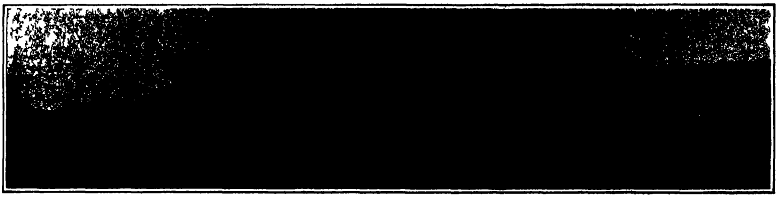
If you could afford to remain at this unique spot throughout a year you would see the sun start on a slowly descending spiral until at the autumnal equinox he would be rolling around the horizon like a big billiard ball The next day he would show only his top edge and the next would disappear entirely for six months slowly spiralling downward until at the winter solstice he is 23 degrees below the horizon and begins his slow return In March he again puts in an appearance repeating his performance of the fall before but in reverse order until on June 21st he is at his highest These would be the phenomena provided you could see them but the chances are that there would be but fugitive glimpses now and then as the snow is drifting almost continually in high latitudes

The auroral displays are of course of common occurrence beyond the circle and at times in the winter become so brilliant as to lighten up the "snowscape" like full moonlight In Franz Josef Land north of Russia the streamers predominate the auroral arch not being common but in the vicinity of the north magnetic pole the arch is seen more often The writer has never been able to hear the peculiar sound resembling rustling silk so often spoken of by Arctic explorers as accompanying a brilliant display And it is his impression that the great magnetic disturbances as observed in the magnetometer in winter are not necessarily accompanied by exceptionally bright auroræ

* Paper [illegible] delivered before the First International Convention of the Society for Practical Astronomy, Port Clyde, Maine.

Where Timber is Wasted

It will surprise most people to learn that boxmakers in the United States use more than four and a half billion board feet of lumber each year or more than one tenth of the entire lumber cut of the country This is the authoritative statement made by the Forest Service of the Department of Agriculture and although most of these boxes are used several times still it is suggestive of a very considerable portion of our fast disappearing forests Already the high price of suitable lumber is forcing manufacturers to seek other materials and more economical methods for packing and shipping their goods, but there is room for much greater developments in this direction



Over the ocean by rail.

To Cuba by Rail

The Last Link Between Key West and Havana Joined

By Harry Chapin Plummer

To Cuba by rail. The dream so cherished by Henry M. Flagler, the founder of the Florida East Coast Railway system, has found its ultimate realization in a wonderful car ferry steamer stated to be the largest and most capacious of her type in the world. This powerful craft, which bears Flagler's name and which is designed specially for the 100 mile run between Key West, Fla., and Havana, Cuba, will complete the final link in the passage of freight without transshipment between the cities of the United States and Havana, Santiago and interior points on the island of Cuba.

At the Havana terminus of the ferry the steamer effects a track connection with the United Railways of Cuba, which, like the trackage aboard the ferry steamer and that of the Florida East Coast Railway, are of standard gage.

Map of the Florida Havana route

In their journey from the north to Key West, trains pass over the $15,000,000 viaduct system that bridges the 107 miles of alternating stretches of water and coral islets lying between the mainland of Florida and Key West. The car ferry steamer "Henry M. Flagler," which goes into service next month, will fill the last gap in the journey to Havana and so fulfill the purpose of the builder of the wonderful chain of viaducts.

It is in the movement northward from Cuba of grape-fruit, oranges, bananas, pineapples and other products of the "Pearl of the Antilles" which are liable to the greatest danger of ruin or injury when transfers are made that the new vessel must prove her worth at the outset. On her southward runs from Key West she will move trains largely laden with dressed beef and foodstuffs originating in the West and the North of this country.

Equipped with four sets of tracks of standard gage on the car deck, which is 360 feet long and provides accommodation for thirty of the largest size refrigerator cars, the ferry-steamer is, in addition, fitted with three cargo holds. These can be loaded either direct from the cars or through cargo ports at the side of the vessel.

The dry cargo capacity of the boat is approximately 1000 tons, with an additional provision in one of the forward ballast tanks for the shipment of a bulk quantity of molasses. Each cargo hold is served by an independent double drum electric cargo hoist of two tons capacity, and the necessary filling and discharging apparatus has been fitted to the tank intended for molasses.

Ten water-tight compartments, into which the vessel is subdivided, are used for ballast purposes. These deep tanks have a capacity of 3000 tons, and the steamer thereby can be brought down to her proper draft when no cargo is carried. A system of pipes connects the tanks, and for emptying them two 12-inch centrifugal pumps have been fitted, which have a capacity capable of clearing all the tanks within an hour and a quarter.

Two triple-expansion engines of the usual marine type, having cylinders 20, 12½, 34 inches diameter by 36 inches stroke, compose the power plant of the vessel, each developing 1,500 indicated horse power at 100 revolutions per minute when operating under 170 pounds steam pressure. The voyage of 100 miles (from dock to dock) is to be made in eight hours—at an average speed of 12½ miles per hour.

The boiler plant will consist of a battery of four Scotch type boilers, each 13 feet 2 inches in diameter by 12 feet long, and each fitted with two 48-inch Morrison corrugated steel furnaces. The boilers will be operated under the "Howden" system of forced draft, and they are built for a working pressure of 170 pounds. The auxiliaries are more than ordinarily complete, the feed, circulating and ballast pumps being duplicated, as is also the electric plant.

A notable feature of the boat is the fine accommodations provided for the officers and crew. Four individual baths are provided for the officers, while the crew's quarters are equipped with four shower baths. Running hot and cold water is furnished for each room, and cold salt water for the shower and bath tubs.

The steamer, the keel of which was laid April 20th last, was built at the Cramp Shipbuilding Yards, Philadelphia, and launched September 22nd. M. O. Furstenau, consulting naval architect for the Florida East Coast Railway, designed the plans and specifications.

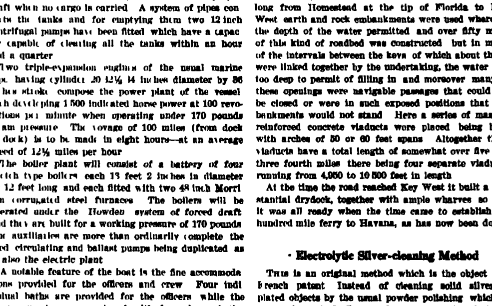
The idea of quick communication with Cuba is not new, for the promoters of the Florida East Coast Railway have had it in view for many years, but the accomplishment has been slow on account of the many difficulties to be overcome. It was no small undertaking to extend the line down the sandy, marshy shore of Florida to Miami, where a long pause was made. Then came that daring engineering feat of carrying a railroad over the swampy tip of Florida and thence by a remarkable series of embankments and concrete viaducts, using the long, curving series of keys as stepping stones, to Key West, the outermost accessible point that can be reached in this manner.

In building this wonderful viaduct, which is 128 miles long from Homestead at the tip of Florida to Key West, earth and rock embankments were used wherever the depth of the water permitted, and over fifty miles of this kind of roadbed was constructed; but in many of the intervals between the keys, of which about thirty were linked together by the undertaking, the water was too deep to permit of filling in, and moreover, many of these openings were navigable passages that could not be closed, or were in such exposed positions that embankments would not stand. Here a series of massive reinforced concrete viaducts were placed, being built with arches of 50 or 60 feet spans. Altogether these viaducts have a total length of somewhat over five and three fourth miles, there being four separate viaducts running from 4,950 to 10,500 feet in length.

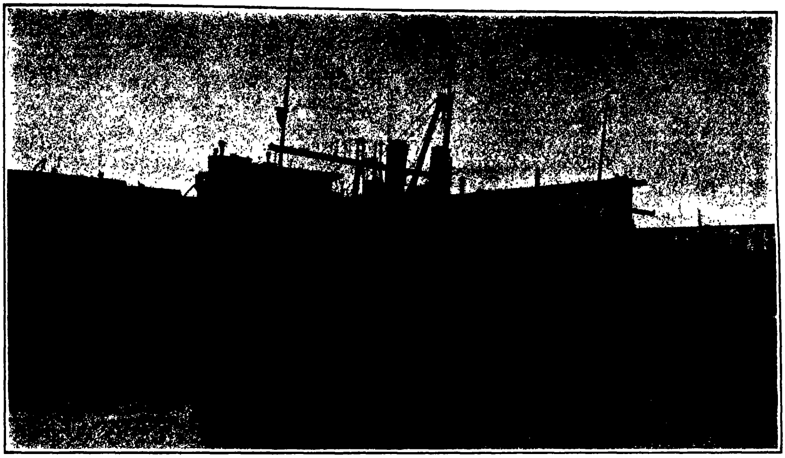
At the time the road reached Key West it built a substantial drydock, together with ample wharves, so that it was all ready when the time came to establish the hundred mile ferry to Havana, as has now been done.

Electrolytic Silver-cleaning Method

This is an original method which is the object of a French patent. Instead of cleaning solid silver or plated objects by the usual powder polishing, which, of course, has a bad effect on the surface, such objects are simply put in a non-metallic basin (enameled ware or the like) and are cleaned by electrolytic action alone. This is done by putting on the bottom of the basin an "electra" plate of specially prepared metal, the bath being a solution of carbonate of soda. From three to five minutes in the bath is all that is needed in order to remove all oxidation from the surface of the silver objects, then rinsing and drying. According to a statement by the Paris Municipal Laboratory, there can be no deterioration of the objects by this process.

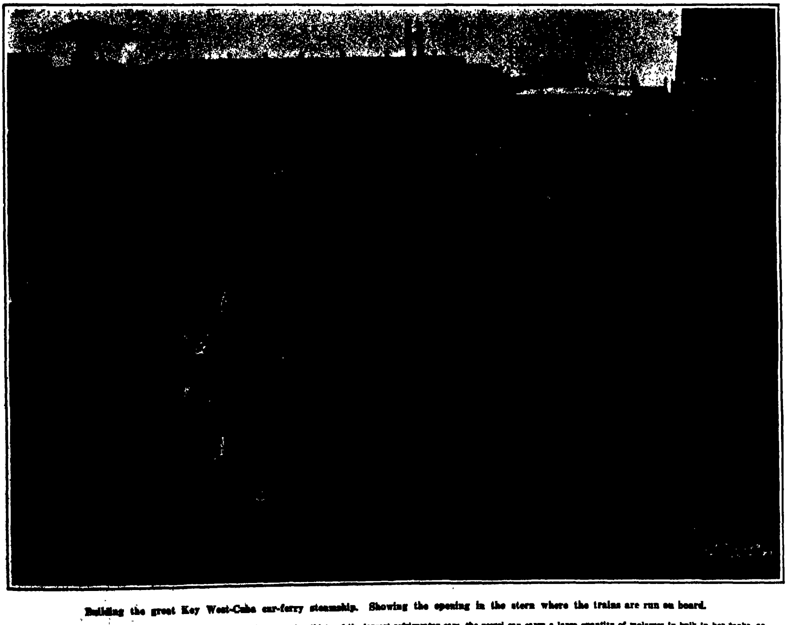


The viaduct that links Florida to Key West.



The car-ferry steamship that transports trains from Key West to Havana.

The trip from Havana to Key West will be made in eight hours, and perishable cargoes, such as oranges, bananas, and pineapples, loaded in cars, will be sent through to any American city without trans-shipment or handling.



Building the great Key West-Cuba car-ferry steamship. Showing the opening in the stern where the trains are run on board.

Four tracks for trains are laid on the main deck, and besides carrying thirty of the largest refrigerator cars, the vessel can carry a large quantity of molasses in bulk in her tanks, as well as much freight.

Apparatus for Demonstrating Newton's Laws

Studying Motion Accelerated Under the Action of a Constant Force

By H. W. Harmon, Grove City College, Grove City, Pa.

Most of the standard text-books in physics and mechanics, under the topic of Newton's Second Law of Motion, give more or less space to the discussion and solution of problems concerning the tensions in cords attached to accelerated bodies, using the cables attached to rapidly ascending and descending elevators for their illustration.

Several years ago it seemed desirable to design an apparatus suitable for our students in the physical laboratory, to test out these principles experimentally. The difficulty met with at once was to find a practical method of measuring these tensions while the bodies were in such rapid motion. Finally, the apparatus shown in the diagram was developed and has been in use by our students for the last two or three years.

As inertia, acceleration, changes of momentum, and reaction are all involved in the experiment, it goes with us under the name of the Newton's Laws Experiment.

Referring to the diagram, Figs. 1 and 2 show a top and front view of the apparatus. The body to be accelerated is a car shown in Figs. 3 and 4, arranged to be variously loaded. It slides over the surface of a hard wood box about 18 feet long and 2-inch by 4-inch section. The car is released from its starting position by the action of the electromagnet (H) shown in Fig. 3, and operated by the clock pendulum, Fig. 2, making and breaking contact. The car is accelerated by the unbalanced weight of the mass M_1, which may also accelerate M_2 if it is attached to the rear of the car, as shown in Fig. 2. The cord connecting the car and M_1 passes over a frictionless pulley mounted on the movable arm shown in Fig. 5. It is apparent by a glance at the spring balance (B) in Fig. 2, that the tension (T_1) in the cord connecting M_1 and the car will be registered by balance B, if allowance be made for the weight of the arm and a slight leverage action of the pulley itself. By this simple scheme we were enabled to measure the tensions in the cord attached to the accelerated body *regardless of the high velocities attained.*

A curve card is plotted in which the weight of the arm and the leverage of the pulley is allowed for, and by its use, balance readings can be taken off from the curve as true tensions (T_1).

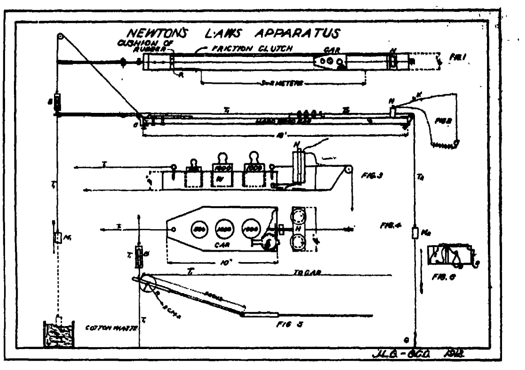
This balance conection is made as follows: With the pulley arm in the horizontal position and the tension T_1 zero, the balance was found to read 125 grammes, owing to the weight of the arm. This weight is included in all cases in the reading of B. But more or less completely neutralizing this weight of the pulley arm is an upward component of the tension ($= 2/32\ T_1$), for as used in this position the pulley, the pulley wheel and arm constitute a right-angled, bent arm lever with power arm equal to the radius of the pulley (2 centimeters), and the weight arm equal to the length of the pulley arm (32 centimeters). With this correction for the weight of the beam, the equation connecting the balance reading B with the tension T_1 will then be:

$$B = 125 + T_1 - \tfrac{1}{16}\ T_1.$$

To draw the correction curve, remember that when $T_1 = 0$, then $B = 125$ grammes; when $T_1 = 125g$, $B = T_1 = 2{,}000$ grammes. Locate these two points on a sheet of cross-section paper by the usual method and draw a straight line through them. (See balance correction curve diagram, Fig. 2.)

To keep the car on the track, the bar has a half round groove formed in it through its entire length, and a corresponding half round runner is fastened to the bottom of the car. To keep the friction constant, the sliding surfaces are kept uniformly polished and oiled with heavy oil. The high velocities attained, 5 meters per second or more in some trials, are reduced without too much shock by the friction clutch and rubber cushion shown in Fig. 1. The velocity of M_2, when attached, is reduced to zero by a spring or gum tube (G) attached to a trailing cord which goes into operation at the same time the friction clutch does on the car, while M_1 is brought to rest in the box of cotton waste shown in Fig. 2.

When the apparatus was first put into practical use the car was released by a trigger operated by hand and the timing done with a stop-watch. Thus operated, the errors due to timing gave results in which the percentage of error was in some trials quite large. Recently we have mounted on the car an electromagnet (H) shown in Fig. 4, which is arranged in series with the releasing electromagnet (H). The armature of this magnet, pivoted to move up and down, has a spring brass wire soldered to it, extending over the back end of the car and bent down near the surface of the sliding track, where it terminates in a piece of chamois skin moistened with well thinned printer's ink. This is shown in Fig. 6 by I. The electric current is led to the car by two wires, one stretched taut down the back side of the bar; the second one is stretched down a second half round groove in the top of the bar. Contact brushes BB for these are shown in Fig. 6. The inker marks off on the bar distances covered in even seconds as beaten



off by the seconds pendulum of the laboratory clock. The slotted weights which go to make up M_1 are so chosen that the unbalanced force in the various trials of the experiment causes the car to make its run down to the clutch in just slightly over 2 seconds.

The inker operates very accurately, for, even in those trials in which the car is traveling 500 centimeters per second, successive trials seldom differ by more than two or three centimeters in the total distance covered in the 2 seconds' time of run used. This indicates that the combined error of the inker and release magnet does *not exceed 1/200th of a second in the timing.* Since equipped with this improved timing device, the apparatus has given very satisfactory results, as can be seen by an examination of the data table. The errors remaining are almost entirely due to balance readings and friction measurements.

The friction is found for each trial as the car is differently loaded. This is done by placing on the weight support, M_1, such slotted weights as will cause the car, when started, to move down the track with a slow uniform motion. In those trials when M_2 is attached to the rear of the car, the total of the slotted weights thus needed, less the weight of M_2, is called the friction.

METHOD AND THEORY OF EXPERIMENT.

First clean, oil and polish the sliding surfaces, then load the car as required and find the friction (F_f) as above. The required weights are next placed on the M_1 weight holder and the car placed at its starting position and held by the trigger ready to be released, following the closing of the electric switch (k) in the clock circuit. When the car is released and is speeding down the track toward the friction clutch, one observer watches the index of balance B, and takes its reading. This is usually repeated three times, and the average reading of B is taken, corrected by reference to the curve card and recorded as T_1.

At the same time, for each of these runs, the distance the car has traveled in 2 seconds, as marked off by the inker, is measured, and these distances averaged ($= S$).

The unbalanced force (F_a), which causes the car and attached masses to be accelerated as it runs down the track, is the difference between the weight of M_1 and the friction (F_f) and also less M_2 if it is attached.

Newton's second law enables us to compute what this acceleration a will be. If absolute units are used, the equation is

$$F_a = Ma,$$

or, using the gramme-weight as the unit of force, and the gramme as the unit of mass,

$$F_a = \frac{Ma}{980}$$

where F_a is the unbalanced force, M is the total mass accelerated, and a the acceleration.

In our present problem the total mass M is given by

$$M = M_1 + M_2 + W,$$

where W is the mass of the car and load. The acceleration a as computed by the formula

$$a = \frac{980F_a}{M} = \frac{980F_a}{M_1 + M_2 + W}$$

(F_a being measured in grammes weight) should agree with a computed from

$$s = \frac{1}{2}at^2$$

$$a = \frac{2s}{t^2}$$

The tension T_2 in the cord connecting M_1 and W is equal to the sum of the frictional force F_f (measured in grammes weight) of the weight 980 M_2 of the mass M_2, if attached, and of the unbalanced accelerating force

$$F_a = \frac{(W + M_2)a}{980} \text{ grams. weight acting on } W \text{ and } M_2.$$

$$\text{Thus } T_1 = F_f + M_2 + \frac{(W + M_2)a}{980}$$

This should agree with the corrected balance reading T_1.

It will be noticed that the tension T_2 in the cord connecting the car with the mass M_2 is not observed experimentally by a balance and movable arm as is the tension T_1 in the leading cord attached to M_1. This could be done in the same way, but it is not deemed necessary for this experimental test to be repeated.

When the car is at its starting position, held by the trigger, the mass M_1 hanging at rest at the end of the cord exerts a tension (T_1) in the cord that is exactly

equal to its weight. The weight of M_2 at rest is fully effective in producing tension. A freely falling body has no effective weight, for its weight force is all used in accelerating it. A falling body only slightly accelerated has a proportional part of its weight effective (i. e., a man in a descending elevator). This effective weight approaches zero as (a) approaches (g) in value when (g) equals an acceleration of 980 centimeters per second per second, or 32.16 feet per second per second; and the weight of a body approaches full effectiveness as (a) approaches zero. We shall therefore expect to find the values of T_1 always less than M_1, and T_2 always greater than M_2, for M_2 is accelerated upward, and T_2 consists of both the weight of M_2 and the force which is accelerating M_2. Reference to the data table shows those expectations realized.

In looking into the factors which enter into this experiment, inertia, momentum, impulse, friction, and tension, it is seen that Newton's Three Laws are all fully involved, and also the laws of accelerated motion. A knowledge of most of the terms used in mechanics is necessary. This therefore should make an especially effective experiment for the junior student in physics or the student making a special study in mechanics.

Sudden Changes in the Form of Liquid Crystals*

By O. Lehmann

FORMERLY science assumed matter to be continuous, although porous; to be chemically as well as physically homogeneous; the molecular arrangement changing of course in case of anisotropy at the border line between differently oriented parts of a body. In case of crystals, which may, however, be defined as aggregates. For example a spherical crystal has been considered an aggregate; whereas, according to my findings, it may be an individual.

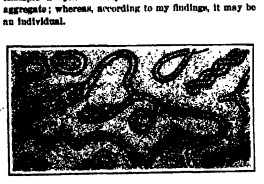

Fig. 1.

Likewise plastically distorted crystals (of gold, silver, etc.) were held to be aggregates of crystal fragments, while the existence of liquid crystals was wholly excluded from the realm of possibility by the "Theory of Identity" (molecular identity in the solid and liquid states), crystallization being made synonymous with solidification, only two sorts of molecular arrangement, the lattice-like order in the crystal and entire irregularity in the molten mass, being considered possible.

My discovery of transparent plastic crystals, whose distortion causes no fragment formation, together with the discovery that by the admixture of foreign substances permanent distortion of crystals can be secured, first justifies the question: "Are such distorted crystals still to be regarded as individual units, or are they aggregates as formerly supposed?" Must we distinguish between true crystalline plasticity, where the crystal remains a unit (for example, soft glass) and apparent plasticity, where a crystalline unit becomes an aggregate of fragments, the only sort of plasticity recognized up to the present?

The further discovery that the form of silver iodide stable above 146 degrees, formerly considered amorphous-viscous, was really crystalline, naturally raised the further question, "Can true plasticity go so far that a crystal may be considered fluid, thus contradicting the 'Theory of Identity?'"

I first obtained absolute proof of the existence of liquid crystals with ammonium-oleate hydrate. The proof rests on the demonstration that these crystals possess no "limit of elasticity," as the term is understood relative to solids; for the molecular equilibrium is automatically restored after any distortion; therefore, the crystals must be considered liquid, not solid.

When liquid crystalline ammonium-oleate is drawn into a capillary tube, the molecules arrange themselves radially, with optical axes perpendicular to the walls of the tube. Now, if a short piece of such a tube is placed in water the liquid crystalline mass swells out at either end into cylindrical myelin forms (liquid crystals), consisting of a modification of ammonium-oleate of identical structure with that in the tube.

Thus the existence of myelin forms is a complete contradiction to the above-mentioned assumption that a chemically homogeneous body must be physically homogeneous, for these myelin forms are not aggregates of crystal units, no boundaries being anywhere observable. Nevertheless, points near the surface are by no means equivalent to those near the axis; therefore *the matter is not continuous. The existence of liquid crystals, especially of the myelin sort, is then a certain proof of the molecular theory.*

The existence of liquid crystals also contradicts the accepted theory that only two forms of molecular arrangement can exist, the one entirely irregular, the other, the lattice-like order in crystals.

If, as I first supposed, the molecules are tiny rods, they must be radially arranged when sucked into a capillary tube; hence any current in the mass would alter the lines of interference, since internal friction would retard motion near the tube wall and give the molecules there situated an oblique direction. This does not occur, therefore I now assume molecules to be tiny flat plates, whose surfaces are perpendicular to the optical axis. Other phenomena support this assumption.

Accordingly a cylindrical myelin crystal is in a sense an aggregate of co-axial cylinders of regularly placed plate-like molecules, these cylinders being closed on the ends by hemispheres of like radius.

This peculiar structure demands anisotropy of thermic motion and of expansile force. The molecules easily glide over one another in a direction parallel to their flat surfaces, therefore expansion in the direction of the cylinder axis is greater than in the direction perpendicular to the axis; the *cylinder must then reach such a thickness that the greater capillary pressure of the hemispherical ends must exactly balance the excess of expansile force.*

It has not yet been possible to demonstrate thermic movements and their anisotropy by the observation of the Brownian movement, and since constant transitions from liquid to solid crystals occur it is very possible that the force hindering the surface tension from compressing the liquid crystal into a sphere (myelin forms) is not alone the force of expansion, but primarily the molecular directive force. A proof of this I believe I have discovered in the peculiar behavior of the myelin forms of ammonium-oleate and of protagon when cooled below — 4 degrees.

AMMONIUM-OLEATE HYDRATE.

At ordinary temperatures the myelin liquid crystals of ammonium-oleate are jelly-like threads, easily bent, showing no elasticity, and no tendency to break even when bent double.

If liquid crystalline ammonia is placed under a large watch crystal shaped cover glass and ordinary ammonia allow to flow around and over the preparation, and the preparation set over night in a cool place, then such myelin forms as shown in Fig. 1 will be obtained. Now place these in a temperature of about — 6 degrees and they will take on the zig-zag shapes of Fig. 2. We conclude that in the softer forms (Fig. 1) the molecules adjacent to one another in the direction of the long axis of a cylindrical surface form very blunt angles with one another; and that the straightening of the cylinders in the stable modification at the lower temperature is to be explained by the combination of the plate-like molecules into complicated molecules, which in turn are flat plates. The work done is a process of *direct transformation of chemical into mechanical energy.*

PROTAGON, PHRENOSIN, AND KERASIN.

Protagon behaves practically like ammonium-oleate hydrate. Phrenosins can be obtained in thin plate-like crystals. The liquid crystals obtained on heating these with water take the shape of cylindrical myelin crystals, resembling ray-like projections, and these on cooling suddenly, shrink suddenly to half their length.

If methelyn blue is added to the water in which phrenosin crystals are allowed to swell, so that the water is only tinged, the crystal becomes intensely blue

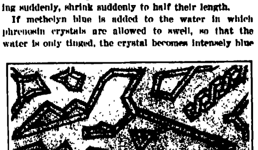

Fig. 2.

(probably through chemical combination). When on cooling the sudden shrinking above mentioned takes place the blue changes to red violet.

Kerasin acts much like phrenosin, expanding and contracting in the same way.

The myelin forms of protagon often lie one within another like the layers of an onion; forms open on one side drawing in, and ejecting smaller forms on solidifying and melting. They remind one of protoplasmic structures. Form and structure are, however, maintained purely by cohesion and molecular directive force, and not by an inclosing membrane.

A Dog-Proof Fence

THE Department of Agriculture in a recent issue of its "Weekly News Letter" tells farmers how to build a dog-proof fence that will safely protect sheep from the ravages of these animals. The posts should be 7½ feet long, set 2½ feet into the ground, and spaced 16 feet apart. Along the surface of the ground stretch a barbed wire, this to discourage any attempts to crawl or burrow under. At three inches from the ground stretch 36-inch woven wire fencing having a 4-inch triangular mesh. Above this woven fencing, and at intervals, respectively, of 5, 6, and 7 inches three strands of barbed wire are stretched, making the total height of the fence 57 inches. This fence is very durable and inexpensive to build, and it is stated that it will keep out any dog.

Forest Fire Prevention

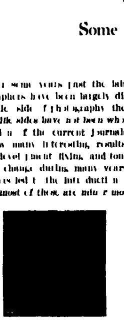
THE prevention of serious damage from forest fires depends largely on prompt information and quick work in checking and preventing the spreading of such fires. In some districts the officials of the Forest Service of the Department of Agriculture have enlisted the interest of residents of their region with excellent results. A recent report of this department states that, in addition to his own fire detection system, the supervisor of the Palisade national forest, Idaho, was notified of each fire by from five to ten different local settlers, who thus showed their co-operation in working for fire suppression.

Recent Advances in Photography*

Some Effects Produced on Sensitive Plates by Material Emanations

By Henry Leffmann, M.D., Ph.D., Member of the Institute

Attention for some years past the labors of many expert photographers have been largely directed to the so-called artistic side of photography; the purely technical and scientific sides have not been wholly neglected and an inspection of the current journals and recent books will show many interesting results. The basic procedures of development, fixing and toning have suffered but little change during many years. The competitive spirit has led to the introduction of many new developers, but most of these are minor modifications of

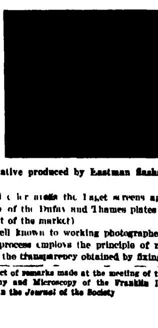


Negative produced by aluminum

the original forms, especially as regards the benzine derivatives, and in some cases the change is in name only. A conspicuous instance of the latter is in the use by the Lumière Company of the terms "pinonict" and "metoquinone" in their formula for color plate work, the information at hand indicating that the names refer to the same substances and that this is merely an intimate mixture of metol and hydroquinone.

Probably the most important, at least the most generally exploited advance in procedure in this field is color photography. It is curious to note that in the first edition of his work on methods of photography, M. Carey Lea stated that in his opinion color photography was impossible and he gave his reasons for this view. Not long after he modified his view in consequence of the results of research, so far as to admit the possibility of such photography. He would surely be interested in some of the plates made to-day by the several processes that are extensively employed, and yet he could truly say that the results obtained by the Lumière, Dufay and Paget plates are not really color photography, but colored photographs in which the hand of the artist has been substituted by ingenious automatic processes.

One of the latest applicants for favor in this line is the Paget plate. This utilizes a color screen involving the same principle as the older methods, that is, an even distribution of the three colors, but in the Paget plate this screen is detachable and hence may be used for many plates. Moreover, the reversion of the image as followed by the older methods is substituted by using the plate as a negative and attaching a viewing screen to a positive made in the usual manner. Paget screens are much more transparent than Lumière screens and hence more satisfactory for lantern demonstration; on the other hand they are much coarser, and a considerable magnification, as when a slide is projected on large extent, shows the individual colors and destroys the illusion. The total cost of a complete Paget lantern slide is slightly higher than that of a Lumière, but if the operator has a considerable proportion of failures, Paget methods are more economical. In sizes of the



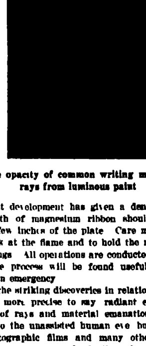
Negative produced by Eastman flashsheet

individual color areas the Paget screens agree closely with those of the Dufay and Thames plates (the latter is now out of the market).

It is well known to working photographers that the Lumière process employs the principle of reversion of image as the transparency obtained by fixing after first development shows all colors complementary. Working with the color plates suggested to me to try some of the reversal processes with ordinary plates, that is, to obtain positives by one exposure. In the early days of negative making, the so-called wet plates, the possibility of direct positives was investigated and several methods were devised. These can be applied to the ordinary dry plates with much success and although such procedures are of no great practical value or wide application they afford an interesting field for experiment by amateurs.

My experience has been principally with the following method:

Good exposure and good development are given, the developer is washed off and the plate stood, coated side outward, in a developing dish of black material (or the plate is backed by black paper) and several inches of magnesium ribbon are burned a few inches from it. The silver deposit acts as a negative and the unchanged silver compounds are light-struck. The plate is then immersed in a solution of potassium dichromate and sulphuric acid such as is used in reversing Lumière color plates until the image has practically disappeared. The plate is washed for a minute or so immersed for a few minutes in a 5 per cent solution of sodium sulphite and then returned to the developer. The second development gives, of course, a positive which is then fixed and washed as usual. Theoretically no fixing is needed, but in practice it is best to put the plate through the regular hypo solution. The second development will usually be rather slow. It must also be borne in mind that plates well wetted by developer are much less sensitive to light than plates in the dry condition; hence



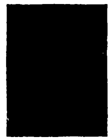
Relative opacity of common writing materials to rays from luminous paint

if the first development has given a dense picture a good length of magnesium ribbon should be burned within a few inches of the plate. Care must be taken not to look at the flame and to hold the ribbon with a pair of tongs. All operations are conducted in the dark room. The process will be found useful for making slides in an emergency.

Among the striking discoveries in relation to light, or it will be more precise to say radiant energy, is the existence of rays and material emanations which are invisible to the unassisted human eye, but affect ordinary photographic films and many other substances and in some cases pass freely through objects opaque to ordinary light.

Upon such phenomena as the X-rays, emanations from radio-active substances, ultra-violet and infra-red light I need not dwell here, as ample discussion of these is to be found in recent literature. I want, however, to call attention to a less exploited field, although even in this the basic procedures are not very recent. I refer to what has been called "picture-making in the dark," inasmuch as the etymology of the word "photography" prevents us from applying it to any processes but those in which light takes part. I need not stop to give any elaborate history of the investigations. An early contribution was that by W. J. Russell before the Royal Society (*Science* 1900, 11, 487), who tried many substances and obtained curious results from some of them. M. I. Wilbert (*Journal Franklin Institute* 1900, cl, 388) repeated some of Russell's experiments with success. In reviewing these papers, however, it seemed to me that in many cases the impression on the photographic plate might be due to pressure or mere physical contact rather than an emanation tangible or intangible. I wish to say frankly that I have failed to obtain many of the results reported by Russell and Wilbert even though following their methods as closely as the descriptions available enable. In the later series of experiments I adopted the plan of interposing thin paper, usually the ordinary lantern mat, between the object and the sensitive plate, thus preventing actual contact. This method materially retards the action.

It has seemed to me that the procedures that I intend to summarize briefly may be called skotography (from Greek *skotos*, darkness). One of the most active skotographic surfaces is obtained by scratching or polishing common zinc battery plates. Thin zinc sheets do not seem to be so active, nor does sandpapering the zinc plates yield very good results. If one scratches on



Tungsten filament. Ordinary plate. Positive (reversal)

a tarnished and corroded zinc plate a design by means of a sharp steel tool and then lays a dry plate (I used ordinary lantern plates) upon this, with a thin paper between, with some perforation or a cut-out design, and allows this combination to remain in the dark for a couple of days, a distinct impression will be made on the sensitive plate that can be brought out by ordinary development. Often the metal is active enough to produce a marked effect in a few hours. Russell expressed the opinion that emanations of minute amounts of hydrogen dioxide produce the effects and that the dioxide is in some way formed by the fresh surface of metal, but I have not yet obtained any information to enable me to form an opinion as to the cause. Magnesium and zinc seem to be specially active; thin sheet iron did not produce any effect. Aluminium has moderate activity. I obtained a strong effect with the so-called flash sheets manufactured by the Eastman Kodak Company. Bibulous paper impregnated with old oil of turpentine gave no appreciable effect, but impregnated with commercial solution of hydrogen dioxide and allowed to get nearly dry before testing gave a feeble picture.

Some experiments have been made on the photographic and other properties of commercial luminous paint. This seems to be composed largely of calcium sulphide in a fixed oil. I have used it on glass plates and have found the most convenient way to get an even coating is to dilute the material with gasoline and pour

Tungsten filament. "Hydra" plate. Positive (no reversal)

the mixture as was the custom with the collodion used in the old wet plate process. When dry the paint forms a somewhat granular, slightly cream-colored film, which will emit for some time a soft, bluish light after a few seconds' exposure to any ordinary source of light; but the most satisfactory results are obtained from sunlight and arc light. Incandescent electric lights, even powerful tungsten lamps, are somewhat slow in action.

Many interesting experiments may be performed with

* Abstract of remarks made at the meeting of the Section of Photography and Microscopy of the Franklin Institute and published in the *Journal* of the Society.

the coated plates. If a piece of ordinary blue and ordinary red glass are placed upon a luminous-paint surface and then exposed to the direct light of an arc lamp for about half a minute it will be found that under the blue glass a strong luminosity is developed, but under the red glass almost no effect is produced. A still more curious effect is that if the entire surface of a coated plate is made luminous and then a portion covered with red glass and again exposed to the light that part under the red will rapidly lose luminosity. The effect may be also shown by covering a portion of the luminous surface with opaque paper and holding the plate near the red light of the dark room. A rapid falling off in luminosity will occur over the surface illuminated by the red rays. I do not mean that the luminosity merely appears less in the red light but it is actually diminished.

Luminous paint may find a practical value in some copying work. Ordinary paper is moderately transparent to it but writing and printing inks are rather opaque. If therefore we render a plate luminous, place it beneath a written or printed page and lay a sensitive plate upon the page (these operations being of course carried out in the dark) it will be found that an exposure of ten or fifteen minutes will suffice to make a latent image on the sensitive plate which can be developed in the usual way. Experiments with gelatine colored with artificial colors have shown that the rays from luminous paint pass freely through violet and blue films but scarcely at all through green and red films and therefore no great difference is noted in the negative obtained when such screens are used with ordinary and with panchromatic plates. The panchromatic plates furnished by the Paget Company which cannot be developed in red light and the common lantern slide plates which may be used freely in red light gave nearly the same negatives. A Lumière color plate was also tried. It was found that no appreciable effect was obtained through the green and red films.

So far as I have experimented the emanation from luminous paints goes equally through glass, quartz, thin films of celluloid, gelatin, barite, calcite and kyanite but this phase of the problem is still under investigation. A photographic novelty of practical value is the Paget Hydra plate. The emulsion of this contains some hydrazin sulphate, a synthetic product which materially controls over-exposure. I have made tests of the plates by exposing them to the light of a 60 watt tungsten within a few inches of the camera for ten minutes. This is sufficient to produce complete reversal by over-exposure in an ordinary plate but reversal did not occur with Hydra plate. Several important uses of such a plate will occur to practical photographers.

Health Requirements for the Aeronaut*

[The letter here published in the form of a much condensed translation was delivered before the Wissenschaftliche Gesellschaft fur Flugtechnik of Berlin and is published in the latest yearbook of that society. The same year-book contains a valuable paper on "The Eyes of the Aeronaut" by Dr. Hilbert while the preceding volume contains a useful résumé of the physiology and pathology of aeronautics by Dr. Friedländer. We regret that we have not space to publish complete translations of these three memoirs as there is comparatively little literature in English on the medical and physiological aspects of aeronautics, important as these subjects are.—EDITOR.]

IN a vehicle of any kind whether of land, water or air the safety of the occupants is more or less dependent upon the physical efficiency of the driver. The degree of such dependence varies however with the kind of vehicle. Thus on a locomotive the place of a disabled engineer can generally be taken for the time being by the fireman while in a dirigible airship the pilot can be replaced by some other member of the crew though such substitution is an unsatisfactory makeshift especially because the man who is disabled is himself likely to require the care and attention of at least one other person. On the other hand in the case of the automobile and of the aeroplane there is generally no question of substitution in an emergency; a very slight degree of physical incapacity on the part of the driver or pilot is likely to be attended with fatal consequences to himself and his companions. In an ordinary balloon the pilot has generally one or more companions but these are not often fully competent to take his place.

So far as these considerations apply to aeronautics, the only possible safeguard against accidents due to the disablement of the pilot is a thorough medical examination of the latter before he obtains his license and the imposition of rigid requirements as to health and physique. Until a few years ago German air pilots were not required to pass any medical examination. Even now the examinations prescribed by the different societies are by no means uniform nor is there any well-defined consensus of opinion on the subject. Hence the following attempt to outline the essentials under this head.

The examination should take account first of all conditions that might lead to functional disturbances under ordinary terrestrial conditions and second to those that while not likely to give rise to serious derangements under such conditions might nevertheless do so under the more exacting conditions that obtain in aeronautics. Some useful hints as to points to which special attention should be directed may often be furnished by the family history. Thus the following questions are absolutely necessary. Has there been in the applicant's family any case of insanity? Epilepsy, or other nervous disease? Alcoholism, Suicidal mania? Tuberculosis? If the answer is affirmative an especially rigid examination must be made of the applicant's nervous system or lungs, as the case may be, and of his personal history with respect to these organs.

In making inquiries as to the medical history of the applicant himself, it is advisable to ask leading questions and to aid the applicant's memory as much as possible, as it is easy under such circumstances to forget or pass over, as unimportant, details of great significance. The following questions will be in order:

1. What illnesses have you had?
2. Have you ever had articular rheumatism, hemoptysis (spitting of blood), hematemesis (vomiting of blood), angina pectoris?
3. Have you ever had any mental or nervous disease, especially one involving lapse of consciousness or attention, etc.
4. Have you ever been injured, especially about the head; broken a bone, suffered a sprain or dislocation? Have you ever undergone an operation?
5. Have you any disease of the eye or the ear?

The answers to these questions should be signed by the applicant.

The portion of the examination blank reserved for the personal observations of the physician usually contains the questions: Is the applicant known to the physician? Has he ever been treated by the physician and for what? To these I would add: Has the physician ever made an air voyage with him? Other questions to be answered by the examiner are:

Does the applicant give the impression of a strong and healthy man?

Physical strength is essential as the task of the aeronaut whether in an aeroplane, dirigible or ordinary balloon is laborious under normal circumstances and may become extremely so as for example when the occasion arises to handle sacks of ballast rapidly.

Are his limbs in any way weak or defective? Are there any malformations of the bones and if so do they interfere with the use of the limbs?

Evidently a pilot needs sound limbs as he may have to climb a rope ladder, ascend the suspension gear of a balloon, climb down from a tree in which his craft has landed, etc. In case a limb has been injured the cure should have so far progressed that no special precautions or nursing of the limb are necessary, otherwise attention devoted to this object may cause inattention to aeronautical duties.

Is the voice strong? Does the applicant stutter to any marked extent?

In any form of aircraft except the aeroplane the pilot will often have occasion to give rapid orders which must be distinctly heard and understood.

What is the conformation of the thorax? Are the lungs sound?

The form of the chest often gives a hint as to the state of the lungs. Tuberculosis should debar the applicant as even in its early stages there is danger of hemorrhage and also emphysema which may become dangerous at high altitudes on account of the difficulty of perfect exhalation.

Is the heart sound? Is there any lesion of the blood-vessels?

Among cardiac troubles we must especially look out for weakening of the heart muscles and valvular defects. This follows first of all from the mere physical labor that may at times be imposed upon the aeronaut. What is true of the heart is also true of the blood-vessels. Even a moderate degree of arteriosclerosis unfits the applicant for such exertions; moreover aside from the danger of rupturing the vessels this disease, by diminishing the caliber of the arteries causes an insufficient supply of blood to the brain; the reduction in the oxygen content of the air at high levels promptly aggravates this condition and disturbs the mental functions causing dizziness, uncertainty of movement, forgetfulness, etc.

As to the effects of altitude on the circulation and breathing, it is not necessary to insist upon the attainment of excessive heights at which the pilot would be expected to resort to the inhalation of oxygen. Provided the apparatus works properly this process is not attended by danger and high flights under such conditions make no special demand upon the physique. On the other hand it is necessary to insist upon the ability to ascend to heights of from 10 000 to 13 000 feet without the use of oxygen and without any diminution of efficiency. The balloonist must expect at times to be carried up to such heights, either on a sunny morning after a nocturnal ascent or in ascending air-currents. I myself recall having been carried up almost instantaneously, during a thunderstorm, from a height of 3 300 feet to over 15,000 feet, while my companion sat in the violently swinging car, helpless with seasickness and altitude sickness. I have heard of cases of altitude sickness at 6 500 feet with nausea, shortness of breath and livid color, while in one case breathlessness and *malaise* began at half this altitude. Evidently a pilot suffering with altitude sickness cannot be depended upon to perform his duties efficiently. In order to test the applicant in this respect, a trial ascent to at least 12 000 feet should be required.

We next come to the abdominal organs. Under this head I think it may be stated that any condition that causes pain or discomfort should be regarded as prohibitive on account of its effect in distracting the aeronaut's attention from his duties. Hernia is prohibitive only in case it interferes with freedom of movement.

Chronic disease of the middle and inner ear must be considered prohibitive, at least in the case of aviators, especially on account of its impairing the equilibrating function of the ear (i. e. of the statolith). Stubborn catarrh of the Eustachian tube may give rise to much discomfort on account of rapid changes in atmospheric pressure but I should hardly go so far as to reject an applicant on this ground. Marked deafness I consider prohibitive.

We now come to the most important class of defects, viz. those of the nervous system. Under this head we may consider separately those derangements that merely affect the motor and sensory apparatus and those that involve mental disorder. Derangements of the first class are easy to detect according to well known methods. We can test for paralysis or muscular atrophy, examine the reflexes, look out for muscular twitching, etc. All nervous affections that impair the strength or accuracy of bodily movements should be considered prohibitive. We can never be sure how rapidly such conditions may become intensified. Thus for example a very slight degree of tabes (incipient locomotor ataxia) is a sufficient ground for rejection.

Among mental affections those characterized by melancholia need hardly be considered as the patients in such cases are not often desirous of becoming aeronauts. Far more dangerous is the opposite condition of exaltation, or hypomania, which is often difficult to recognize from external indications and which may lead to impulsive and reckless acts.

Incipient paralysis is especially dangerous. Every possible precaution must be taken to exclude such cases; whenever suspicion exists not only should the medical history of the applicant be thoroughly investigated but decision should be reserved and a reexamination made after a lapse of time. As paralysis is so commonly a result of syphilis and as it may be extremely dangerous even in its early stages when diagnosis is difficult, I am inclined to apply the same rule to the aeronaut that Dr. Placzek has laid down for railway employees, and exclude all syphilitic applicants though I admit that this is rather sweeping.

Mild cases of epilepsy are not susceptible of diagnosis in the intervals between seizures; they can therefore only be detected by a careful investigation of the medical history.

Alcoholism, the more severe forms of which can be readily diagnosed, is absolutely prohibitive.

We have lastly to consider a variety of nervous disorders which are as a rule easily detected and recognized in ordinary medical practice when the patient voluntarily confides his symptoms to the practitioner but which are by no means so easy of diagnosis when the patient is undergoing examination for a pilot's license and is anxious to avoid rejection. These include neurasthenic and hysteric conditions as well as ordinary "nervousness." They can be detected only by means of actual ascents under an experienced pilot who should report all abnormal actions on the part of his pupils to the medical examiner; the latter will decide what importance should be attached to them. Most aeronauts are more or less nervous and upset before an ascent. Seasickness when due to the imagination rather than to the actual movements of the balloon-basket, excessive timidity, strong aversion to looking downward, the desire to jump overboard and hallucinations of various sorts are all to be considered in deciding upon the fitness of the applicant. Whether any of these common manifestations should be considered prohibitive in certain cases must be left to the judgment of the physician, who should preferably be himself an aeronaut.

* Abstract of a letter by Dr. E. Koschel.

"Suction" Between Passing Ships—II*

Important But Little Understood Forces Affecting the Motion of Vessels

By Sidney A Reeve, M E

Continued from SCIENTIFIC AMERICAN SUPPLEMENT No 2036, Page 32, January 9, 1915

The form in which the stream line ship derived mathematically from sources and sinks was left by Mr Taylor's last addition to its theory was still unsatisfactory for the analysis of suction between actual ships. Its outline was everywhere convex. Stem and stern were both rounded, there was no hollow entrance or run, and the middle body was not parallel. While such a ship form might do for the study of the general principles (which indeed could be well understood without any stream line analysis) yet for any estimate of *quantitative* aspects of the problem a better ship-form must be had. The magnitude and exact form of the constrained wave accompanying a typical steamship could be had only by mathematical deductions which were based upon a typical ship model having a long parallel middle body, hollow entrance and run and sharp prow and stern.

To the writer it appeared likely that Taylor's method might be made to yield these results provided a suitable function of sources and sinks could be found to form the premises. This could be determined only by the cut-and-try method which as each try involves tedious repetition of simple computations proved to be laborious. However the nineteenth function tried gave a fairly satisfactory model as may be seen from Fig 7, the ship form in which is a mathematical stream line and not an assumed form, and upon that model all the curves and contours presented here are based.[1]

Taylor's method was modified slightly in order to facilitate the work of investigating many different premises by taking a large number of points and relying upon averages rather than integrating a separate curve for each one of the thousands of points investigated, yet even with this the method is laborious. The ship's length was divided into twenty parts and in terms of these longitudinal units and for each one-fifth the beam extending laterally the stream lines were computed over a sea-surface extending nearly a ship's length forward of the stem and nearly two ships lengths abeam. In this work only one quadrant from the course ahead to either beam need be computed because the mathematical treatment makes the four quadrants symmetrical. But in actuality the viscosity of the water and the energy lost in wave-making make the constrained wave astern smaller than that ahead.

This plan would apparently give over two thousand observations in each quadrant but in the regions farthest from the ship many points were omitted the contours there being of less curvature. Taylor's intermediate curve was plotted on a sheet 4 feet square the largest practicable in this case and final values of stream line widths were computed to four decimal places (provided by a characteristic) with intermediate computations carried to five or six places. Students repeating this work will do well to plan for greater accuracy than this for whatever scale is adopted at the start must be adhered to throughout the work. The stream-lines were all drawn as accurately as possible, but the computed values were charted thereon and formed the sole basis for deduction no values being taken off graphically except in the use of the intermediate curve where precautions were taken to have the graphical work sufficiently accurate.

Fig 7 gives the results for a single ship. The model has a beam one-eighth its length, with a parallel middle-body of half its length sharp stem and stern, and slightly hollowed entrance and run. The draught was taken as four tenths the beam. The curves are true for a relation of speed to length indicated by any of the following proportions from which other lengths or speeds can be interpolated but the numerical scale of elevations will vary with the square of the speed, that noted in Fig 7 being true only for an 500-foot ship going at 20 knots

Length ft	200	300	400	500	650	800	1000	
Speed knots	10	12	35 14	14	15	82 18	08 20	22 37

The curves of Fig 7 are level contour lines. For readers not familiar with the preceding article, it may be repeated that these contours show not actual elevations or depressions of the sea, but surpluses and deficits of sea-pressure in an imaginary sea having just the depth of the ship and confined by a thin sheet of rigid ice on its surface. These are assumptions necessary for practicable mathematical treatment but it is obvious that while the vertical release of the water under actual conditions would vary these curves somewhat yet their relative disposition cannot be far from those shown.

Through the center of the ship's displacement are drawn the 45 degree lines which would be its mean sea-level contour if its displacement were reduced to a single point. Asymptotic to these lines are the approximately hyperbolic mean sea-level contours due to the elongated form of the ship. These hyperbolas extend indefinitely away from the ship, but all the other contour-lines are closed curves or would be if the diagram were sufficiently extended.

Between the limbs of each hyperbola ahead and astern of the ship rises an oblique cone of water at stem and stern, reaching an altitude of 8 feet above mean sea-level. This altitude it is to be remembered, is *exclusive* of the bow waves or stern waves. It is relatively to this conical surface that these waves raise their crests and depress their troughs. While the peak of this constrained wave is sharp its base is very broad. At a distance of half a length ahead of the stem the sea is elevated 3 inches over an area extending more than a length athwart the course. But on either beam the depression of the sea is still more marked in extent. For five-eighths of a length out away from either rail the sea is a foot or more below normal level while the 3-inch depression extends out to a distance probably of several lengths not measurable on the diagram. It is thus wider area of depression than of elevation which probably has given the name suction rather than repulsion,' to the phenomenon. It is noticeable that the deepest depression does not occur directly abeam but on either bow or quarter where occurs a pocket reaching a depth of 9 feet. From this point the water line rises to less than 5 feet below normal sinks again to more than 5 feet where the curvature of the bow alters to the straight lines of the middle body finally rising to less than 4 feet at mid length. The peculiar form of the 4-foot curve led to its being checked by a fresh computation for that district upon a larger scale, but the result only confirmed the earlier curve, strengthening the writer's confidence in the virtual accuracy of the entire diagram.

The symmetry of these constrained waves as between bow and stern depends not merely upon the assumption of perfect fluidity in the sea-water, but upon levelness of sea-bottom. Should the ground beneath the ship be rising this constrained wave will be in process of formation to the magnitude shown, from the smaller constrained wave of deep water, and this formation must take place first at the bow. This explains how it is that a high-speed boat such as a destroyer will feel a bank many feet beneath its bottom, so forcibly as to fetch the crew up against rails or bulkheads. As the bow passes over the bank this cone of water must form ahead while the stern has yet no corresponding cone pushing it ahead.

These contours also explain how it is that a ship's resistance is so markedly increased in shoal water. It also explains how a high-speed boat seems to settle in the water. One case is reported where a paddle-steamer failed to come to speed on her trial trip, it being found finally that her paddles had not been located with a view to this depression of the water on either beam so that before she attained full speed the floats lost their full contact with the water. In all ships of appreciable speed having a painted water-line the uncovering of the underbody throughout the greater portion of her length by the trough of the constrained wave is plainly visible. The heaping of the water about her stem is more or less obscured by the bow-waves, but at the stern although the stern-crest is smaller than the bow-crest, the regathering of the water under the counter is usually plainly to be seen. The importance of a fine run for taking advantage of this phenomenon is apparent when it is noted that in the model of Fig 7 the amount of energy constantly being stored in the constrained wave-is some 40,000 horse-power. The bulk of this power is being as constantly regained at the stern, but because of the viscosity of the water, not all of this enormous supply comes back. It is the office of the ship's run to regain as much of it as possible.

III Interaction Between Two or More Ships.

The problem of determining the distortion of the sea-surface in the neighborhood of two ships moving on parallel courses, and overlapping, which is the standard position for the development of suction forces, is impossible of exact mathematical solution, so far as the writer is aware even with the aid of the imaginary sheet of ice and the restriction of the water to motion in horizontal directions. But the stream-line method offers at least two ways of securing approximations to the truth which are near enough to shed very much more light upon the situation than is available in our present state of knowledge.

The first method consists in taking two sets of stream-lines identical with Fig 7, overlapping them in the relationship between the two vessels which is to be investigated and then adding them.

The result of such a procedure is shown in Fig 8, which is derived from two ships like Fig 7, placed on parallel courses a half-length apart, with one ship lapping a quarter-length over the other. The resultant stream-lines and sea-contours are quite accurate, but they have now lost their practical value as being founded upon ship-models fairly typical of actual ships. For the models secured by this mathematical method are themselves fluid (until we imagine them momentarily solidified) and therefore each ship-model has now become warped narrowed, and distorted by the influence of the sources and sinks forming its neighbor. The beam has been reduced about one-half, the axis of the model is no longer straight nor co-incident with the intended course, while the general heading of each model has been sheered away from its neighbor.

All of these features tend to minimize the mutual hydraulic reaction due to the solidity, in actual practice, of the neighboring hulls which is called 'suction." Nevertheless Fig 8 shows plainly, in comparison with Fig 7 the general directions in which the sea-contours about each ship are modified by the presence of the other. First, following out the 45-degree lines from the center of displacement C common to the two ships, it is evident that the area of superpressure included in the hyperbola ahead of the leading ship must be unsymmetrically placed. All the curves depicting the cone of superpressure ahead of the leading ship corroborate this view. Her head is being steadily pushed to port more than is visible in the small scale reproduction of the curves.

But it is also true, as could not be predicted from the general disposition of the 45-degree lines, that the head of the following ship is also being pushed to port by a cone of superpressure ahead, which bears much more obliquely than in the case of the leading ship. It is the pressure of this cone of water into one side of which the following ship is always heading, which crowds her over towards the other's quarter. It is the rapid exaggeration of this cone, both in altitude and obliquity, by the piling up of the water displaced by the leading ship, as soon as the following ship yields at all to its insistent pressure, which explains the suddenness with which suction collisions occur, and the complete unmanageability of the following vessel as soon as she is permitted to head in the slightest degree towards the other.

It is also to be noted that in Fig 8 the altitude of all four cones of water has been exaggerated, both in comparison with Fig 7 and with each other, for, since the beam of the vessels has been halved, the cones of Fig. 8 should naturally be only 4 feet high, and the same at each end of the ship. But in Fig 8 the cones at the overlapping ends are nearly 8 feet, and at the distant ends well over 5 feet, in height, or nearly a quarter larger than proportionate to Fig 7. At the same time the larger cone constantly retards the progress of the leading ship, while accelerating that of the following vessel.

One of the earliest instances of hydraulic interaction between following ships ("Narragansett"–"Providence," in 1869) witnessed how this last-mentioned feature may lead to the actual towing of a slower consort for considerable distances by the leading and slightly faster of two vessels upon parallel courses in restricted waters, purely by "suction." This is what is called in America a "wireless tow." The phenomenon may not result in collision. In the case cited the "towing" continued for several miles. The final collision, occurring in Hell Gate, may or may not have been materially aided by suction forces. The notion is common in [illegible] [illegible] [illegible], although late, [illegible] the pilot of a following vessel may [illegible]

* Reproduced from *Engineering*

[1] Students should be cautioned that all writers on this stream line topic complain of the labor and tedium of computation. The writer appreciated this only after he had become involved. The processes are simple and anyone in command of a corps of clerks could easily carry the Taylor method to further and better results than are here presented. But anyone attempting to investigate alone as a spare-time occupation, must be prepared for very slow and tedious progress.

his ship is being "picked up" or accelerated by the faster ship which has almost passed When this occurs, although collision may not be inevitable, it is a sign that his ship is in unstable steerage, and that the first irregularity of sea-bottom, or projecting pier or even the approach of some otherwise harmless third vessel, may precipitate a disaster against which all his skill and engine power will be unavailing But even a slight sheer away from the other ship, taken in time will suffice to avert it

One method by which Fig 8 might be developed into a set of contours or typical ship-models would consist in starting all over again from initial functions of sources and sinks which would be arbitrarily selected upon curvilinear axes (convex towards each other) and of double strength, so judged that when the two sets of stream-lines were added the effect would be to straighten out the hulls into normal shape on straight parallel axes. But this method promises an exaggeration of even the laboriousness inherent in the work reviewed thus far While its fruits would be mathematically exact, and therefore worthy of full confidence its penalty in the form of labor was too forbidding for the writer's command of leisure and an easier side step was taken around the difficulty

This consisted in going back to the original set of stream lines from which Fig 7 was developed and superposing them as for the preparation of Fig 8 but then regarding the two hulls as remaining solid This method gives very closely the volume of water entrapped by each stem as it cleaves its course which volume must find its way aft as best it may constrained by solid hull and sea bottom and superficial ice The question then remaining is Along what stream lines does this water distribute itself?

This question cannot be answered mathematically but the guidance provided by the composition of Fig 8 permits a fair estimate to be made as to how the exact stream-lines would be influenced by the additional water entrapped on each side of each hull by the solidity thereof The estimate thus applies merely to a minor correction of values already obtained with mathematical accuracy, and, although the form of the contours is influenced considerably by the method of correction adopted, it is thought that the result is fairly accurate It at least shows accurately the direction in which Fig 8 would be modified if the hulls were solid and the amount of correction in this direction might easily be more than that shown in Fig 9 This diagram I would therefore style a mathematical conjecture

The mathematical form of correction must be one easily applied to thousands of points in repetition The one most readily suggesting itself in view of this requisite and of the facts become familiar during the preceding work, was to assume that the surplus or deficit of water entrapped by the stem is distributed over the sea-surface away from the ship's side in what amounts to a logarithmic curve, approaching zero as the distance increases indefinitely That is to say, it was assumed that 1/nth of the surplus or deficit was retained between the first two stream-lines, 1/nth of the remainder between the next two, and so on The factor n was given a different value arbitrarily, in the light of the preceding work, for each different point of the ship's length.

Whatever criticism may be directed at the choice of this particular method of distribution, it is beyond question that the true stream-lines for two solid hulls like Fig 7 must consist of a distortion or correction of the stream-lines on which Fig 7 was built by some factor which has its greatest effect at the ship's side, with a gradual dissipation of that effect with lateral distance which can never become complete Considering that the uncertainty applies to a minor fraction of a minor correction the form of the resultant contours depending chiefly upon the particular localities in which a positive or negative correction is appended to a previous positive or negative departure of stream line from parallelism rather than upon the magnitude of the correction itself it is believed that Fig 9 is worthy of credence as offering the only approximation to the truth regarding following ships which has yet been offered from even a semblance of a mathematical basis

The contrasts between Fig 9 and Figs 7 and 8 are numerous and interesting In the first place whereas Fig 8 is inevitably symmetrical from its mathematical origin in the sense that it makes no difference in which direction the two ships are moving in Fig 9 this is no longer true Owing to the different surplusage of water entrapped by the two stems which surplus must then travel throughout the length of the solid hull before again exerting its influence upon the water on the other side of that hull the contours about one hull are appreciably different from those about the other The oblique cone of water ahead of the following ship is quite different both in magnitude and angle from that following the leading ship The excess of pressure from one quarter over the other which is the principal force membering that the steering of any ship depends upon the horizontal moment developed between the rudder forces at the stern and the center of lateral resistance C (which is always well forward in the direction of the ship's motion) It again becomes obvious why it is that it is usually the following vessel which is diverted from its course Until Fig 9 was developed this explanation had to depend upon the fact that the following vessel was usually the smaller and weaker Now, however it appears that the forces at work upon the after vessel are so much larger than upon the leading ship even when the ships are of equal size and speed that the following vessel must still be the one more liable to diversion from her course even when somewhat larger

As to speed it is not evident just what difference it would make as to relative forces The suction forces are the mutual product of the two ships acting cooperatively They are the result of the aggregate rate of displacement by the two vessels so that any increase on the part of either ship must result in the exertion of increased divertive forces upon both

Fig 10 should make it plain why it is that a vessel in the grip of suction forces pays no attention to a hard over helm Making every allowance for the exaggerated vertical scale the length of after body far from the center

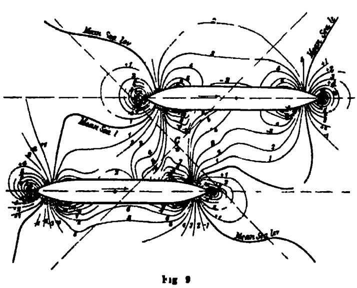


Fig 9

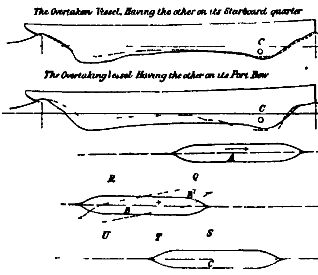

Figs 10 and 11

acting to sheer the ship off her course is much greater in the following than in the leading ship which explains again how it is that it is usually the following ship which is deflected

In general however Fig 9 which is really derived by a quite different and independent line of reasoning from Fig 8 corroborates that diagram The leading ship is seen to be sailing continuously up-hill against a cone of water at its stem which is 3 feet higher than that at its stern while the following ship is likewise sailing down-hill all the time into a relative hollow of equal depth This is caused by the leading ship's shouldering the burden of displacing the water for both of them the reaction from which displacement rises under the stern of the following ship and aids her progress

In Fig 9 the pairs of cones of water ahead and astern of the ships respectively are each merged into a single hyperbolic cone asymptotic to the 45-degree lines whereas in Fig 8 they were separate but this is because in Fig 9 the ships lap by four-tenths of a length whereas in Fig 8 they lapped by only a quarter length It is probable that a slightly greater lap than four-tenths would exaggerate the mutual distortion of contours and the development of suction forces but the labor of computing even a single relative position was so great as to be prohibitive of any comparative investigation of different ones In Fig 9 as in Fig 8 the lateral distance between the two courses is a half-length but in Fig 9 the beam of the ships reduces the minimum distance between hulls to about 0 385 of a length In both diagrams the full line contours are those drawn through computed points while the broken lines indicate where the contour was interpolated by estimate

While Fig 9 gives the best foundation from which to estimate the effect of variations from its particular arrangement of dimensions of hulls the results of this particular arrangement can best be seen in the form of profiles of the water-lines of the two ships—assuming again that the computed pressures of Fig 9 might be translated into actual elevations of water by the removal of the imaginary superficial sheet of ice without altering the values Such profiles are given in Fig 10 in which the vertical scale is exaggerated five-fold for better visibility They are plotted directly from Fig 9

On each profile is shown a conventional center of lateral pressure C, taken at one-fifth the ship's length from the stem Comparing the two profiles, and re- of lateral resistance which is exposed to a head of several feet of water pressure acting laterally is overwhelmingly larger than any lateral force imaginable to be developed by or on a rudder It is utterly impracticable to build or navigate ships so as to defy suction forces These forces can only be avoided and that only by foresight

But the most important question of all Why do not suction collisions happen frequently and why do they happen unexpectedly in situations apparently encountered frequently before in safety? remains to be answered The answer involves the third wall of the Venturi passage-way between the two ships namely the sea-bottom or else some equivalent outlying factor not yet brought into the discussion

Figs 9 and 10 are based upon a degree of propinquity which is seldom reproduced in actual navigation even disregarding our mathematical assumptions of imaginary ice etc That is to say ships seldom move at full speed on parallel courses within half or third a length of each other in water barely sufficient to float them The explanation of why suction collisions do not occur is that even a moderate deepening of the water below their draught rapidly moderates the forces at work so that by the time the water is deep enough to permit full speed it is deep enough to make fairly close overlapping courses safe The explanation why suction collisions do occur when they do is usually the fact that a moderate contribution of solidity to the ship's environment by sea-bottom or by a third vessel or an accentuation by even a slight convergence of courses is competent to exaggerate back into control those forces which the previous depth of water had rendered innocuous

For deep water while reducing the intensity of the constrained wave correspondingly increases its volume or extent and it also permits increased speed on the part of the ship It is when the ship passes suddenly from deep to shallow (or otherwise limited) water that trouble arises This great volume of constrained wave moving at a speed above that attainable by the ship in uniformly shallow water piles up into a degree of intensity which it could never assume in uniformly shallow water If it begets disaster it does so by suddenly releasing an enormous accumulation of energy which the ship has been carrying with her in addition to that currently at work

A glance at Fig 9 will show how rapidly all the con-

ditions creating suction will be exaggerated by any angular swing of the following ship toward the leading one. The two pockets, 11 feet deep, on her port bow and starboard quarter are there because a surplus of water is trying to get to its ultimate destination, which is off her port quarter, as rapidly as possible. To give it the necessary horizontal acceleration a drop in head must occur. But how much more will this region off her port quarter lack its supply of water if the bow swings toward the leading ship, cutting off the channel between them, while the stern swings out, lengthening that route for the water?

But what most commonly happens is that while the courses remain parallel the ships run over a hump in the sea bottom, or they pass a pier-head or bank, which, when opposite the trailing ship's starboard quarter, reduces the pathway for water, and therefore deepens the pocket on that portion of the hull - the former being the more common cause of disaster. Such a combination of circumstances will instantly exaggerate into uncontrollability suction forces which previously -perhaps during a considerable period of overlapping -had proven harmless. It may be that the vague fear of suction, so often mentioned by pilots as felt when steering such following courses, had been stilled by such preceding period of security, only for the relaxation of alertness just at the time when the alteration in the depth of water created the real danger. Too many suction collisions occur just where the water shoals slightly to permit disregard of this factor, although it is impossible to bring it into any mathematical discussion Nor are the data of actual disasters sufficiently accurate so that the shoal can often be located exactly, in relation to the ships, when action occurred. But it is seldom that unquestionable suction occurs when only the two ships are present, surrounded by open water.

A similar contributing factor in many of the minor cases occurring in American inland waters is a third vessel. Fig. 11 shows how such a combination may produce disaster. *A* and *B* are ships moving in the same direction on parallel courses and overlapping. *C* is a third ship upon another parallel course. If *C* be moving in the same direction as *A* and *B*, *B* is plainly (from Fig. 9) steering in very unstable equilibrium, sailing steadily down-hill into the pocket created by the displacement of *A* and *C*. The slightest swerve of *B*'s head towards *A*, as at B^1, will not only starve the *Q* region of water needed at *R*, as would be true if *C* were not present, but will trap an over-supply of water between B^1 and *C*, exaggerating the pocket at *U* and creating an additional one at *T*. *B*'s head will be crowded towards *A* and her stern and middle body drawn towards *C* with irresistible forces, which grow stronger with every additional degree of swing.

Not only are there several instances where this situation has led to disaster after two of the three ships (say *A* and *B*) had sailed closely but safely for some time, but there are a few cases where the only plausible explanation of an otherwise inexplicable sheer of *B* into *A* was that *C* had exerted this same effect, even although passing in the opposite direction. These are all in the restricted channels connecting the Great Lakes, used by boats of heavy tonnage; but the speed was correspondingly low, a circumstance minimizing the danger of suction.

Only two attempts have been made, to the writer's knowledge, at the experimental determination of suction forces. One was the Taylor experiments with models in the Washington towing-tank already mentioned These observations confirmed in every way the hydraulic theory already presented. They were limited in their educational value, however, by the fact that the models were fixed relatively to each other, thus preventing any knowledge as to how rapidly these forces are enhanced by the natural swing of the vessels towards each other. Any determination of this acceleration will, of course, be very difficult; but since it is quite impossible by mathematical analysis, and is virtually impracticable even with models (because the prime question is whether such action occurs more or less rapidly, in full-size ships, than the human organism can act), it is unfortunate that the ideal ships of the British or United States navies cannot be utilized for this purpose. When suction was the thing anticipated and under measurement, it would be easy to make the experiment safe.

The other known set of experiments was made with actual vessels, if small ones, by Prof. A. H. Gibson and Mr. J. H. Thompson (reported in *Engineering*, September 27, 1912). These experiments also corroborated hydraulic theory in every respect. Their chief drawback was the inequality in length between the two boats, as well as their small size. One, a steam yacht, used as the leading vessel, was virtually three times the length of the other, a motor boat. From Fig. 9 it will be obvious that it is important that the two ships be at least similar in length. In one prominent suction collision, however—the "Brockton"-"Hartt"—the leading boat was much larger than the attracted boat; and in this instance, too, arose a beautiful example of interaction between the constrained wave of the smaller boat and the echelon wave of the larger (the two waves being of similar length) as the contributing cause which converted an otherwise safe situation into a disastrous one. This collision is further the more remarkable in that it occurred in comparatively deep water, outside Sandy Hook, between vessels of comparatively light draught.

There will be given a brief description of a few of the more prominent or illustrative suction collisions. Anyone who has studied the entire list of such recorded disasters will be impressed with the clear way in which all but a very few are explicable as natural, if not inevitable, phenomena, so soon as the foregoing hydraulic theory is applied. But he will also be impressed with the variety of combinations of circumstances which may arise to create suction forces powerful enough to produce disaster, and thus to record themselves in civil suits at law. These combinations are too many to be always remembered, nor can the list of possible ones be already exhausted We have not yet finished with suction disasters. While channels are continually being deepened, longer, deeper, and more powerful hulls are appearing at an even higher rate of progress.

For these reasons the subject cannot be dismissed without at least a word as to the possibility of preventing future suction collisions. The general education of pilots is one obvious measure of relief, and it is to that end that the present article is primarily aimed. But another more formal and reliable preventive is feasible, in the writer's belief, and this is an amendment to our international navigation laws covering the case of overtaking vessels. The suggested amendment (which is offered tentatively, by one who is not a certificated navigator) should read to this effect:

That when an overtaking vessel asks for and receives from the leading vessel permission to pass, by the exchange of the usual signals, the acquiescence of the leading vessel shall enforce upon both vessels the slowing of their engines, those of the following vessel being reduced to "half speed," and those of the leading vessel to "slow," which condition is to be maintained until the overtaking vessel's stern has passed clear of the overtaken vessel's bow. In restricted waters such a procedure is the only safe alternative to the overtaking vessel remaining astern until wider sea-room has been reached.

(*To be concluded.*)

The Inductance of a Coil

To the Editor of the SCIENTIFIC AMERICAN SUPPLEMENT:

IN the SCIENTIFIC AMERICAN SUPPLEMENT of October 10, 1914, appeared an article by Kenneth Richardson, in which was given a formula for the calculation of the self-inductance of a coil.

I wish to call attention to the fact that the formula as given is, in general, inapplicable, and of no practical use for the purpose stated in the article. It is "exact" only in case $\frac{D}{l}$ = a certain value, where "D" is the diameter, and "l" is the length of the coil. The quantity "101.5" has a different value for every change of $\frac{D}{l}$. Using K for "101.5" the formula may be written:

$L = \frac{N^2T^2}{l} K$ where:

L = Inductance in centimeters.
N = Total turns.
T = Radius, centimeters.
l = Length.
K = A constant, depending in value upon $\frac{D}{l}$

The calculation of the constant K is a long and difficult matter and beyond the ability of the average amateur radio experimenter. Likewise, the calculation of the self-inductance of short solenoids is by no means simple when accurate results are required.

To illustrate by an example the error if one uses the formula given by Mr. Richardson: I shall take a coil which would be suitable for use as the primary of an oscillation transformer for amateurs. Dimensions of coil:

D = 20 centimeters, or 8 inches (approximately)
T = 10 " " 4 " "
l = 10 " " 4 "
N = 8

where

D = Diameter
T = Radius
N = Total turns
l = Length

Calculating the inductance of the above coil by Nagaoka's formula we get: 13,277.6954+ centimeters, or 13.2776954 micro-henries. This value is extremely accurate, as checking with the absolute formula of Lorenz, the difference is only 0.057+ of one centimeter.

Calculating the self-inductance of the same coil by the formula: $L = \frac{101.5\ N^2T^2}{l \times 1000}$ we get 25.984 micro-henries, as the approximate self-inductance.

From the foregoing it is evident that the error for a coil in which $\frac{D}{l} = 2$ is approximately 95 per cent.

In order to have gotten highly accurate results we should have had to use 51.865+ instead of "101.5," in the case of the coil which we considered where $\frac{D}{l} = 2$.

In the above case the self-inductance is the current sheet value and requires a correction, depending upon the size of wire used, for the true low frequency inductance. If we use No. 4 B. and S. wire, the self-inductance will be 1.0546662 micro-henries greater, approximately. The low frequency inductance then is: 14.342+ micro-henries. Knowing the self-inductance exactly, the method of obtaining the dielectric constant as described by Mr. Richardson is simple and should be suitable for amateurs. But the self-inductance cannot be calculated with the required accuracy by the formula given, excepting, as before stated, in the case of a coil of certain dimensions.

RAILROAD ELECTRIFICATION IN THE FAR WEST.—[See page 56.]

Malaria and the Transmission of Diseases

Radical Improvements Needed in Public Health Methods

It is curious that though the transmission of disease is a matter of such vast import to every one of us, it has received so little investigation in the past. Even up to the middle of last century our inquiries had led us little further than what I call the subscience of the subject—that is, we distinguished, classified, and named our various bodily inflictions. Bacteria are easily saprophytic and may have many paths of transmission, and I fear that we are still very much in doubt as to the most important of these numerous routes.

Some of the largest parasites were known in antiquity, but the ancients possessed quite a wrong notion of their origin, which they attributed to spontaneous generation. In the seventeenth century, however, Redi proved that this hypothesis does not hold for certain insects; and later Pallas argued that parasites originate *ab ovo*, like other animals—that is, that their eggs escape from one host and enter another host, thus leading directly to the presence of the parasites in the latter. This history possibly still holds for certain parasites; but in 1790 Abildgaard showed by experiments that some parasites of fish live not only in those fish, but a part of their existence in certain water fowl; and this extraordinary law, which may be called after De Barry's term, slightly changed, the law of metaxeny, was proved during the middle of last century to apply to a large number of Platodes and Cestodes. Subsequently Leuckart, Meinikoff, and others extended the law to cover other species, including species of Nematodes. A most important case was that of the *Filaria medinensis*, the famous guinea worm of man, which was shown by Fedschenko in 1869, following a suggestion of Leuckart, to be in common with man and a water flea (*Cyclops*). All this constituted a discovery which was both remarkable in that it exhibited the wonderful devices of nature for propagating parasites from host to host, and was also of the higest importance to mankind (though few recognized this point at the time) because it showed us how many of our great diseases are likely to be acquired.

Let me dwell on this point for a moment. Parasites, accustomed as they are to dwell in the safe retreats of certain portions of their host's body, must be exposed to great dangers whenever they come to pass, as they must do, from one individual host to another. Thus, if this passage is effected merely by the egg, it is obvious that the eggs must be poured out in immense numbers to compensate for their immense destruction outside the body of the host, while it would always be probable that only a very minute proportion of the eggs would ever find their way again into fresh hosts of the proper species. In order to avoid these difficulties, nature, I presume through an infinite period of evolution, has enabled many parasites to acquire a more safe and certain route of entry—through other animals which are associated frequently with their first species of host. Remember that nature is as solicitous for parasites as for the higher animals which contain them. She thinks no more of man than of the minute germ which infests him.

Following upon the discovery of Fedschenko, Manson in 1877 showed that the embryos of another *Filaria* of man (*Filaria bancrofti*) develop in a species of mosquito, probably a *Culex*. The life-cycle of this parasite, up to the point to which he carried it, was closely similar to that demonstrated by Fedschenko for *Filaria medinensis*; and Manson did not complete the story. Lastly, in 1880, Laveran made the most important discovery that malaria is associated with a minute protozoal parasite of the blood; and his observations were followed by those of Danilewski and others who showed that similar parasites are to be found in many animals.

But up to the last decade of last century we still could form scarcely any definite idea as to how the protozoal parasites pass from one individual host to another. The law of metaxeny which had been proved to apply to many of the larger parasites had not been extended to the smaller ones. In 1889, however, Smith and Kilborne discovered a small parasite called *Piroplasma*, in the blood of cattle suffering from Texas fever; and more than that showed that in some mysterious way the infection is carried from ox to ox by means of certain cattle-ticks—though they did not demonstrate in any way that these parasites undergo a metaxenous stage of development in the ticks, and indeed failed to find them at all in these arthropoda. In 1896 also Bruce made his famous discovery that the Trypanosomes of nagana are conveyed by certain tsetse flies, but supposed that the carriage is a mechanical one. And there the matter rested until the solution of the great malaria problem opened up to those interested a new field.

We now turn to the subject of malaria. Economically, as well as medically, it is certainly the most important disease in the tropics, perhaps in the world. It is found almost everywhere in hot climates, and even in most temperate climates during the summer. From statistics we find that as a broad general rule in malarious countries about one third of the total population suffer from attacks every year. But these figures are merely based upon records and do not cover the enormous additional number of patients who remain untreated.

It is remarkable that even more than 500 years before Christ the ancients certainly were acquainted with one great law—namely, that malaria is connected with stagnant water, such as marshes; and there are good grounds for believing that Empedocles of Sicily actually delivered Selinus from malaria by draining its marshes or by turning two rivers into them. This knowledge seems to have been generally held since ancient times, though it must have been acquired quite empirically; but Varro and Columella, at about the time of the Christian era, actually suggested that the disease is in some way connected with insects which breed in marshes. In more modern times, however, malaria has been ascribed to noxious vapors given off by stagnant collections of water—the hypothesis evidently being that the poison is some kind of chemical one. Even ten years after Laveran's discovery we were still completely ignorant as to how the malaria parasites enter the body.

At the same time, however, the hypothesis originally but vaguely mooted by Varro and Columella had been gaining ground. Indeed, Lancisi had repeated the same speculation in 1717 and seems actually to have suspected mosquitoes and to have studied them. In 1883 Dr. A. F. A. King wrote a most able paper on the subject, in which he gives no less than 19 reasons why mosquitoes are likely to carry malaria. He thought that the insects bring the poison from the marsh and inoculate it into men. Next year Laveran himself and Robert Koch independently enunciated the same speculation, but gave few reasons and no experiments in support of it. Ten years later, however, Manson repeated the hypothesis, but in a different form. By this time (1894) the parasites of malaria had been very carefully studied, and were shown to possess, not only certain forms which are provided for their propagation in the human host, but also other forms which, when the blood is freshly drawn, emit several so-called flagella. These latter forms had really led Laveran to his discovery, but their zoological significance still remained quite unexplained. Manson now urged that the flagella given off from these forms are really flagellated spores; that when mosquitoes ingest blood containing these forms the flagellated spores escape in the insect and enter its tissues, where they ripen into some further unknown stage. Then, he thought, the insect dies two or three days later on the surface of the water, and this later stage of the parasites enters the water, and finally rises in the marsh-mist to infect men. Obviously, therefore, Manson's hypothesis was quite different from King's: the former thought that mosquitoes derived the parasite from men and transferred it to the marsh, while King thought just the opposite. Neither really reached the truth: both were half right, but half wrong.

I was first drawn to the malaria problem in the year 1880, when I observed during active service in Burma that the prevalence of malaria did not at all accord with the theory of the telluric and marsh miasma. If the poison is given off in an aerial form, either from water or from soil, the disease ought to be almost uniformly distributed. Such, however, is not the case, and it really occurs principally in very small spots or pockets, generally in close proximity to stagnant water. Thus in one station where I subsequently served my regiment was severely inflicted, while other regiments, scarcely a mile distant, remained almost entirely free.

In 1907 I observed another variety, which I called dappled winged mosquitoes, and which everyone now knows were Anophelines. I first saw these in an intensely malarious quarter near Ootacamund, where I myself acquired malaria during my investigations. A few months later I obtained sight of these insects in Secunderabad, and employed them for my usual experiments. Six of them died or gave bad dissections. On August 20th, 1897, I was so fortunate as to find in the tissues of one of these insects, four days after it had been fed upon a case of malaria, certain bodies which I had never observed in mosquitoes before. These contained the characteristic pigment of the malaria parasite. Next day, the 21st, I found the same bodies in the last mosquito of my batch of eight—only they were now larger and more definite. A little later I found the same bodies in two more mosquitoes and knew that I was on the right track: I felt that the two unknown quantities of this complex equation had been simultaneously found—the species of mosquito which carries malaria, and the position which the parasites take in its tissues, namely, the wall of the intestine.

Unfortunately, my work was now interrupted for nearly six months, just at a point when I expected to unravel the whole history of the malaria parasites in a few weeks; and it was not until March of next year that I was able to take up the thread again in Calcutta. In a very short time I was able to demonstrate the presence in mosquitoes of pigmented bodies derived from the allied parasites. These bodies were found to grow regularly during one week after the insects had been fed; to reach maturity, and to produce a number of elongated spores. Now came an intensely exciting moment. What happens to these spores? According to Manson's hypothesis, they ought to liberate themselves in the water in which the insects died; but I had now shown that the insects did not die after two or three days as he supposed, but may live for weeks. I attempted to follow the spores in all directions through the insects' tissues, into the lower intestine, and even into the egg. On July 4th, 1898, however, I observed the fact that the spores enter the insects' salivary or poison glands. The full truth was now immediately disclosed, and proved to be far more wonderful than any of us had ever dreamed of. The parasites are not only taken from man by the mosquitoes as Manson had supposed and are not only put into man by the mosquitoes as King had supposed; but both hypotheses are true, and the insect carries the parasites directly from man to man. Here then was merely another case of the great law of metaxeny—which, however, was now proved for the first time to hold good for protozoal parasites. The malaria parasites, like many large ones, require two hosts for their life-cycle.

In July and August I infected 22 out of 28 healthy birds by the means of the bites of infected *Culex*—thus completing the whole story in detail. True, that was done with birds' malaria, and I had only seen the first steps of the process with regard to human malaria; but any zoologist will know that with such closely allied species the life-cycle of one is sure to be almost exactly similar to the life-cycle of the other. My work was now interrupted again, and for nearly a whole year; and it was not until August, 1899, that I was able to show directly that the human parasites have exactly the same development. Meantime, however, Koch and Daniels had confirmed my work on birds' malaria; and certain Italian workers repeated it with regard to the human parasites, even to causing infection in healthy human beings (November, 1898), three months after my similar work with birds.

A very important discovery had been meantime made quite independently by MacCallum and Opie in America (1897) who showed that the bodies which Manson had thought were flagellated spores were really sperms. Thus the large pigmented cells which I had found in mosquitoes at the same date were really fertilised macrogametes. This gave a much more correct zoological interpretation to my phenomena; but did not otherwise disturb the history which I had ascertained.

The discovery of the full life-cycle of the parasites enables us, not only to "precise" the route of infection, but to determine exactly which species of mosquitoes are concerned. Since then the work of many observers has shown that out of about 500 Culicidæ only about 25 species carry malaria, and that all of these belong to the Anophelines. So that for the prevention of malaria we are not obliged to deal with mosquitoes in general, but only with particular species.

Another discovery, concerned with one of the most important of human diseases—namely, yellow fever, was made by Reed, Carroll, Lazear, and Agramonte during the last days of last century. Without knowing the causative agent of that disease, they yet showed by direct experiments on human beings that the infection is carried directly from man to man by another species of mosquito *Stegomyia fasciata* or *calopus*. It had long been stated by epidemiologists that malaria is connected with damp and decaying vegetation, and the latter with insanitary conditions round houses. The former hypothesis was verified by the observation that Anophelines breed in terrestrial waters, and the latter was now explained by the fact that Stegomyia breed in artificial collections of water round houses. A little

* Abstract from the Huxley lecture, delivered by Sir Ronald Ross, at Charing Cross Hospital.

later Graham gave strong evidence in favor of the theory that dengue fever is carried by a species of *Culex*. Thus mosquitoes have now been incriminated as the carrying agents of no less than four important diseases of man. But this is by no means all. I have mentioned that Bruce incriminated *Glossina morsitans* as the carrying agent of nagana and he and others now showed that the deadly sleeping sickness of Africa is carried by other tsetse flies. Various Spirochætes especially that of tick fever have been shown to be conveyed by ticks. A peculiar type of comparatively mild fever of which the cause like that of yellow fever is still unknown has been proved to be conveyed by sand flies. Several diseases of animals have been proved to possess a similar history and others both of animals and men are suspected to lie in the same category. Perhaps however the most important and dramatic result was that obtained in the case of plague the most terrible of epidemic diseases the wonder and the despair of humanity since the beginnings of history the scourge which was so often attributed to the direct action of God. It is caused really by the rat flea. And this discovery signals another advance because plague is as we all know due not to an animal but to a vegetable parasite and we therefore see that bacteria also may adopt precise routes of entry. A similar case is that of Mediterranean fever which is carried principally by the milk of infected goats and leprosy (another supposed scourge of Heaven) has been attributed to the bites of bed bugs while some are even beginning to think that measles is due to fleas.

We now have a great sanitary ideal put before us—so to manage our habitations villages towns and cities that the vermin in them shall be reduced to the lowest possible figure. Scores of entomologists and medical men are now dealing exactly with the habits of these creatures and showing us how to effect the required object. It demands only intelligence, energy and organization on the part of administrators. Unfortunately these qualities are not always forthcoming and administration often lags years behind the dictates of science. Although 15 years have elapsed since many of the facts which I have described were discovered I think that I may say after constant study of the subject and with all due consideration that mankind has hitherto not effected more than about one-tenth of the improvement of health which it might have effected already if it had put its heart into the business.

Applied Electrical Science in 1914*

Wide Field Open to Research as an Aid to Practical Application

By Prof A E Kennelly †

THE year 1914 will undoubtedly be signalized in the history of our world by two great epoch making events namely the opening of the Panama Canal and the opening of the world wide war. Both events may be classified as relating to engineering or applied science the one being an engineering event of international constructiveness and the other an engineering event of international destructiveness. Both have distinct relations to electrical engineering and both are doubtless destined to leave their impress upon human affairs for many generations. Nevertheless we may well hope that in the long run the constructive effects of the canal upon international activities will outweigh the destructive effects of the war.

INFLUENCE OF THE PANAMA CANAL

The influences of the Panama Canal are manifestly destined to be more potent on civilization than those of the Suez Canal because to use an electrical analogy the route short circuited is greater. The Cape of Good Hope lies approximately in south latitude 35 degrees whereas the Magellan Straits lie in south latitude 5[?] degrees. By means of the new short-circuit the whole world is virtually made smaller and the nations of the Pacific are brought into greater relative prominence. Electrical machinery and long distance electrical control with their concomitant modes of thought not only actuate the locks of Gatun but will carry their stimulating influences to all parts of the Pacific. The center of gravity of the world's engineering activities must necessarily undergo some displacement.

THE WAR'S EFFECT ON ELECTRICAL ENGINEERING

The war has already exercised notable effects upon electrical science. On research applied investigation and all that goes to pave the way for advancing engineering knowledge it has laid a heavy hand of repression many young men having been taken from the laboratories of Europe to trenches fortifications and graves. The influence of this setback is likely to be felt in scientific research for many years to come.

On the other hand the war itself has had a remarkable influence upon particular branches of electrical engineering and notably on radiotelegraph engineering. This has been stimulated by the needs of maintaining communication between co-operating forces separated by considerable distance especially as submarine cables have been intentionally cut in a number of places. Hostile cruisers have commandeered and erected radio stations while they have also been captured by means of notices sent out through other radio stations. For the first time in the world's history we have witnessed the regular use of radio transmission across the Atlantic by one of the belligerent powers for the dissemination of daily war bulletins. Radio communication has also been employed in the field along the astonishingly long lines running over hundreds of kilometers while aeroplanes have also been equipped radiotelegraphically. Battle fleets have kept their ships in touch with radio signals and 'jamming' between hostile signalers is now recognized as a regular weapon in the new ethereal warfare. The whole war has depended upon engineering as never before.

This is a gasoline war in which transportation to the armies in the field beyond rail head has depended vitally on automobiles, advances of troops on the ranges of the most improved type of rapid fire cannon and naval contests on the results of shooting at distances not less than 8 kilometers. It is manifest that next to discipline and *morale* engineering is most important in war.

Another instance of the stimulus which war may give to engineering is afforded by the decision which has been recently announced in the press that, in view of the satisfactory experience last year with the electro magnetic drive on the United States naval collier Jupiter the United States Navy Department intends to try electromagnetic variable-speed drive between steam turbines and propellers on a new battleship. On such a ship the demand for high fuel economy over a wide range of speeds is particularly great. Nevertheless if the electromagnetic drive proves very satisfactory on warships it may be possible to extend its application to commercial vessels.

IMMENSE FIELD FOR ELECTROMAGNETIC RESEARCH OPENING UP

Turning to more tranquil themes the year just passed has witnessed a remarkable development in the electrical theory of the atom. It is only about two years since Dr Laue discovered the remarkable effects of the interference of Roentgen rays passing through thin crystal plates. This discovery appears to have set ajar the door of a new world which many pioneers such as Moseley and Bragg are rapidly opening.

The world of our immediate recognition may perhaps be described as commencing with the linear magnitudes revealed by the ordinary microscope and ending with the linear dimensions of the earth's diameter a range in round numbers from a micron or meter-sixth up to some 10 000 kilometers or a meter-seven a total range of ten million million. Beyond this we recognize a telescopically revealed world of upper magnitudes commencing say at a meter-seven and going up to what limit we know not but employing measures of decades of light years and light is supposed to travel in one of our years through nearly ten million millions of kilometers or a meter thirteen so that the upper magnitude world may be estimated in round numbers as from a meter seven to a meter fifteen or through an explored range of about one hundred million. There is now opened to our comprehension a third and lower magnitude world commencing say at a micron where the ordinary microscope stops owing to the relative coarseness of light waves and descending to we know not what lower limit but already it is said to an infinitesimal part of a micron that is to the X ray wave length. The world of our immediate cognizance thus comes between an upper magnitude telescopic world with no known upper limit and the new lower magnitude X ray microscope world or underworld with no known lower limit. The underworld is also an electrical world in the sense that its dynamics and modes of exploration are essentially electromagnetic. Already the explorers in the underworld are explaining to us from the results of their measurements some of the mysteries of crystalline structure and holding out possibilities as to the yet deeper mysteries of atomic structure. An immense field for electromagnetic research seems to be opening on the borderland between ours and the underworld as the result of discoveries in 1914.

While notable progress has been made in the investigation of extremely short electric waves progress has also been made during 1914 at the other end of the spectrum or in the extremely long electric waves of long distance radiotelegraphy. Ranges powers and wave lengths have all been advancing. Moreover marked advances have been made in the construction of very high frequency machines for radio communication. It would seem as though the progress of engineering in long-distance radiotelegraphy called for the design of exciters of sustained oscillations in the sending antenna as distinguished from exciters of oscillations in separate groups.

Steady progress has been witnessed during the year in the direction of the manipulation control and knowledge of high tension phenomena in relation to transmission lines including corona losses and over voltages. Energy transmission lines have increased in voltage number and length.

APPLIED SCIENCE OF ILLUMINATION

In the applied science of illumination there has been a tendency to increase the use of the lumen or unit of luminous flux and to diminish the use of the candle or unit of luminous intensity. The tendency has been fostered by the difficulty which presents itself in the photometric measurements of certain new types of lamp in which the zonal distribution of light is more than ordinarily complex. In so far as the tendency is parallel to similar movements in the past development of electrics and magnetics it is presumably to be regarded as an advance.

In the direction of standardization of electrical machinery the publication by the American Institute of Electrical Engineers of a new edition of its Standardization Rules constitutes a distinct step in advance. The new edition is not only a great improvement upon the old but it also covers much more ground owing to the collaboration of many specialists in the various branches of electrical engineering. The new rules have not only presented a fine series of technical definitions but they also abolish the antiquated preceding notion of an overload capability to be expected in electrical machinery like a bonus on a stock transaction. The new order of ideas in regard to thermal rating allows of no overloads in regard to temperature but it establishes clearly the principle that each and every type of electrical machine inherently possesses a certain hot test spot temperature that should not be exceeded if the particular insulating material entering into the machine is to be preserved from injury. Consistently with maintaining this limit of temperature the capability of the machine to carry load depends upon the temperature of the machine and the cooling powers of its environments so that in winter weather with low surrounding temperatures a machine may be capable of carrying considerably more load than in a hot engine room or at a summer temperature. Under specified conditions of ambient temperature the rated load may be obtained.

Stereoscopic Photographs

STEREOSCOPIC photography possesses numerous advantages over ordinary photography. Many subjects which in the ordinary photograph are in no way interesting and appear insignificant have a fresh and surprising charm when standing out in the relief of a stereoscopic photograph. A note in the German journal *Prometheus* in quoting the *Photographische Rundschau* on this subject, says that the large bare foreground often necessary in photographs of buildings monuments and the like enhances the subject of the photograph to a striking degree when that subject is presented in the relief of the double form. The romantic wildness of mountain regions, curious formations of rocks and foaming water-courses make a far stronger impression stereoscopically than in ordinary pictures. The same is true of the many and changing aspects of the sea as the sea in repose, waves breakers effects of sun light and moonlight on the sea mirages and reflections caused by light on the water small boats ships etc.

There are excellent kinds of stereoscopic outfits so that the amateur can obtain these advantages without a very heavy tax on his purse.

New Light on the Great Toothed Divers of America

Remarkable Bird Forms of Prehistoric Times

By R. W. Shufeldt, M. D.*

For many years past the world has known of Prof. O. C. Marsh's discovery of the toothed birds. Their fossil remains showed them to belong principally to two widely separated groups of bird forms, either one of them possessing the extraordinary, though not altogether unlooked for character of true teeth. This discovery was made in 1870, the fossils having been obtained near the Smoky Hill River in western Kansas, the region where we find that geological horizon of the Middle Cretaceous known as the "Pteranodon Beds."

As the Cretaceous formation is earlier than the basal Eocene, and the latter having an age of some three millions of years, we may gain some idea of the vast lapse of time since these toothed birds flourished. When they came to be studied and classified they fell into two main genera, the one being represented by *Hesperornis* and the other by *Ichthyornis*. Prof. Marsh's great work about them is now known far and wide throughout the world, and figures of the restored skeletons of *Hesperornis regalis* and *Ichthyornis victor* have been published with text matter about them in nearly every quarter of the globe in several scores of tongues. They have appeared not only in all sorts of scientific books, but in every day magazines as well as in school and college text books.

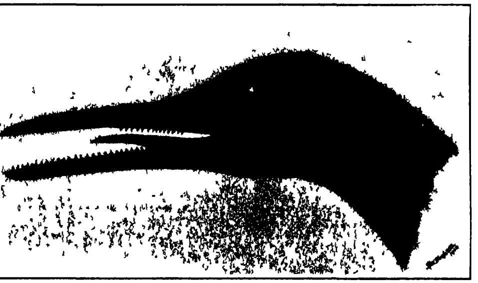

Fig. 3.—Left lateral view of the head of an adult Hesperornis regalis, as it may possibly have appeared in life. Restoration by the author, with proportions taken from a type skull by Marsh

Prof. Marsh made some very unfortunate errors in the sumptuous volume just referred to, for he announced that "the Struthious characters seen in *Hesperornis* should probably be regarded as evidence of real affinity, and in this case *Hesperornis* would be essentially a carnivorous swimming ostrich."

This and other statements made by Prof. Marsh in his description of the form in question have since been proved to have been grievously incorrect, for it has been shown beyond all manner of doubt by Prof. D'Arcy Wentworth Thompson of University College (Dundee) and by myself that not only was *Hesperornis* an immense cretaceous diver or loon, but that *Ichthyornis* should never have been compared with a tern (*Sterna*) in order to throw light upon its affinities, for its skeleton shows that it is more nearly related to our black skimmer (*Rhynchops*), as I have pointed out elsewhere long ago. Finally, while Marsh's *restoration* of *Ichthyornis victor* and its near allies is probably quite correct, it is more than can be truthfully said of his restored skeleton of *Hesperornis regalis*, for no bird of its skeletal organization could possibly have stood in any such attitude as he has it. It is ridiculous in the extreme, and it is about time that it be superseded in our text books by a figure presenting the bird, or rather its skeleton, in a natural pose.

In the United States National Museum there is a mounted restoration of the skeleton and its restored parts, which shows very correctly the swimming posture in so far as the skeleton goes of this great extinct diver. Mr. Charles W. Gilmore is largely responsible for this excellent piece of work, and it will go a long ways toward correcting the gross errors of Marsh in the public mind. No doubt were Prof. Marsh living to-day he would be the first to admit his misconception of the form, habits and relationships of these remarkable birds, and especially those of *Hesperornis*. Moreover, he was not the only one during the latter part of the last century who entertained incorrect notions in regard to these toothed aquatic forms now extinct for nearly four millions of years, for the author of the present article slipped up in several particulars along the same lines.

As long ago as 1890 I published in the *Century Magazine* of New York city an article entitled "Feathered Forms of Other Days," in which numerous figures, reproductions of my own drawings, appeared. Among these was a restoration of *Hesperornis regalis*, which represents the bird perched upon a partially submerged limb in the water. The attitude was suggested by Audubon's figure of the Florida Cormorant, as I have elsewhere said, and this was commented upon, years ago, in my correspondence with the late Prof. Alfred Newton, F.R.S., of Cambridge, England. No *loon* would be likely to climb up on a limb of a sunken tree in any such manner, indeed, as the legs of *Hesperornis* were oar-like paddles that protruded *laterally* from the *sides* of its body, it would have been quite impossible for it to have performed any such feat. As to the tail and feet *per se*, they probably are much nearer the truth. That *Hesperornis* had a big tail composed of true feathers there can be no doubt in the world, while its webbed feet, each possibly having the *contour* of the cormorant's foot, was nevertheless, structurally more likely of the kind we find in any of the great modern divers, such as our great northern diver or loon (*Gavia immer*).

My interest in this subject has been recently revived through what has been brought to my notice from two different sources. The first of these occurred through the kindness of Mr. Charles W. Gilmore, who has charge of the fossil reptile and bird department in the Division of Palæontology in the U. S. National Museum. During the latter part of September Mr. Gilmore and Dr. T. W. Stanton of the Division of Geology of the U. S. National Museum were together exploring the region known as Dog Creek in Fergus County, Montana. They were in search of fossils and were the first scientific explorers to visit that region since Prof. Marsh was there a great many years ago. It was nearly in the exact locality where that geologist discovered the fossil remains of a big bird, which he subsequently named *Coniornis altus*, publishing the fact that he believed it to be allied to the aforesaid *Hesperornis regalis*; in other words, that it was a toothed diver related to the extinct cretaceous loons of western Kansas.

The country where this specimen was found is rugged, mountainous and extremely desolate, as will be seen by referring to Fig. 1 of the present article, which is a reproduction of a photograph made by Mr. Gilmore and kindly presented to me for the purpose for which it is now being put. A few months ago I had the opportunity to carefully study the type of Marsh's *Coniornis altus*; the result of my examination will appear later on in another connection, it being somewhat too technical to be touched upon here. This much may be said, however, the bones found by Prof. Marsh belonged to a big toothed diver, and that in itself is extremely interesting, not to say important, for it was generally believed that these extraordinary birds were restricted to a much more limited area, that is, to the Cretaceous beds of western Kansas.

Now the exploration of Dr. Stanton and Mr. Gilmore in this region was by no means barren of results, for the first named scientist was so fortunate as to discover on Dog Creek, one mile above its mouth on the left hand side of the valley (Fig. 1), the fossil remains of still another large bird, and this valuable material has likewise been submitted to me for description. I find it to belong to a large extinct toothed diver and is extremely interesting when taken in connection with our studies of *Hesperornis*.

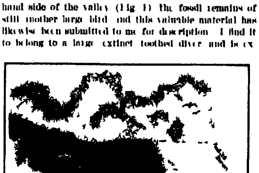

Fig. 2.—Sketch given to show the exact locality of the discovery and the geological formation. By the author.

My research upon this fossil has been completed and fully illustrated. It will appear, later on in *The Auk*, of which Dr. Witmer Stone is the editor. The exact locality where this fossil was found is shown in Fig. 2 of the present article. The exact spot is there indicated, which is seen to be the bed assigned to the Claggett formation; it is a marine one, and at this point is overlain by the fresh water deposit of the Judith River.

These discoveries go to show that these great ancient

*Corr. Member Zoöl. Society of London; Fellow Amer. Ornithol. Union; Hon. Member Royal Australasian Ornithol. Union, etc.

loons with teeth had, in cretaceous time, a very wide range over the country now known to us as western North America, and that there were probably numerous species of them, as I have pointed out in papers which, at the present time, have been accepted for publication.

Hardly had I finished with the discovered *material* just referred to when I received from my distinguished friend, Mr. Gerhard Heilmann of Copenhagen, the third part of his excellent work now being published on "Our Present Knowledge of the Origin of Birds" in the official Organ of the Danish Ornithological Society. This very thoughtful and painstaking piece of work contains much that is both new and interesting in regard to *Hesperornis*, for Mr. Heilmann is one who is not satisfied unless he goes to the very bottom of things. In my opinion this naturalist's conception of what kind of a bird, including its structure, this giant, cretaceous loon was like now stands among the best of those which have appeared up to date.

As did D'Arcy Thompson and I, or even more thoroughly, Mr. Heilmann has compared the material as given us by Marsh in his *Odontornithes*, representing hesperornis with the corresponding skeletal structures of loons, cormorants and other birds. This exhaustive study convinced Mr. Heilmann that the nearest living allies of the cretaceous loons are the large divers of the present avifauna, as *Gavia* and its near allies in the same family and genus. He is of the opinion that the feet of *Hesperornis* were completely webbed as in the cormorants, which view I do not recall having seen advanced by any American palæornithologist. That the true feather elements are found in the chicks of ostriches and their near allies, the emus, cassowaries, etc., and missing in the adult forms, is excellent evidence pointing to the fact that these now flightless birds are descended from forms which possessed the power of flight as well developed as in any of the best fliers of the present day. As they, in time, lost the power, the plumage *degenerated*, and the wings with the flight feathers atrophied. There can be no question but that all existing birds, whether strong fliers or those in which that power is more or less abrogated, are descended from ancestors which possessed it to the highest degree; for if this were not the case they were never birds at all, but animals of some kind, as those of some reptilian order. A beautiful living example of a bird that is now losing its flight is Harris's Cormorant (*Nannopterum harrisi*) of the Galapagos Island. This bird is a true cormorant which, with its atrophied, degenerated wings, is thoroughly incapable of flight. Its wings have gradually become shrunken from non-use; and, although perfect as wings, they have become useless to the bird for the reason that they are nowhere near large enough for the use of a bird as big and heavy as this cormorant. Its wings were not needed because the bird, being a *fisher*, on lonely islands where it had no enemies, very rarely took to flight, and as a consequence the unused limbs gradually shrunk in size until the bird could not fly, even had it the desire to do so. Recently I prepared an account of the skeleton of this cormorant and it will soon be published by the Zoological Society of New South Wales, Australia. In the plates accompanying it the atrophied wing-bones are well contrasted with the rest of the skeleton and exhibit their diminutive size and feeble development.

When we come to discuss the color of the plumage of *Hesperornis regalis* we not only pass into the realm of pure conjecture, but we are, at the same time, confronted with a question about which very little has been written. All of our now-existing American divers (*Pygopodes*) have white bellies, so it is fair to presume that the entire under parts of *Hesperornis regalis* were white. Mr. Heilmann says "whitish-yellow." Judging from the Great Northern diver (*Gavia immer*) and its near relatives, the Pacific loon, the yellow billed loon and other species, it is almost safe to say that the upper parts were of a bluish or greenish *black*. It is likely, too, that the upper parts and neck were longitudinally striped, with stripes composed of squarish or roundish white spots—small on the neck, but increasing in size as they passed to the back and on, diminishing gradually again posteriorly.

The grounds we have for making a surmise of this kind lie in the fact that the young of many birds and mammals present a plumage, or, in the case of the latter, a pelage, which is marked with longitudinal rows of spots, and these are lost when the bird or mammal assumes its adult coloration. This is well exemplified in the young of the loons, the emus, the cassowaries, and, among mammals, the tapirs, the deer, the wart hogs, etc. In some deer the longitudinal spotting remains throughout life, as in the axis deer (*Cervus axis*).

Now, it is a well-established law in phylogeny that very frequently the *young of existing* mammals and birds assume a pelage or a plumage which closely resembles the coloration of the *adults* of their very remote ancestors. This being the case, and especially as the young existing loons are spotted, it is quite or even more than likely that the ancestor, *Hesperornis*, of our present-day loons had rows of longitudinal spots adown its upper parts, and, as I say, on a ground color of a black or a bluish or greenish black.

Mr. Heilmann ably advances this theory in his work; I fail to see any reason for its not having been the case, and a good deal of likelihood that it was. In Fig. 5 of the present article I present a photographic reproduction I made from a plate in his Part III, which was made from his original painting of a group of cretaceous loons (*Hesperornis*), as they may have appeared during the time in which they flourished. Basing it upon conjecture along similar lines, I have also made a drawing of the head of an adult *Hesperornis regalis*, which is here reproduced in Fig. 4. This is somewhat less than the size of nature and was modeled over the skull shown in Fig. 3, which I photographically copied from Marsh's plate, reduced in the same proportion as Fig. 4 (Plate XX, *Odontornithes*), and which gives the entire skeleton half natural size. In my figures the individual bones are lettered, their names being given in the legend. This has never been done before in the case of this extinct, toothed, cretaceous loon, and I trust it will be of use to comparative avian osteologists.

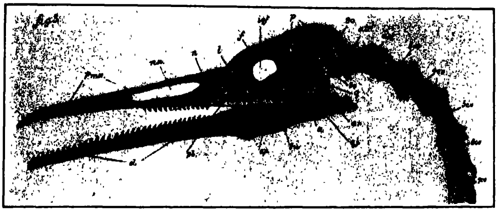

Fig. 4.—Left lateral view of the skull and leading seven cervical vertebræ of Hesperornis regalis; less than half natural size. By the author after Marsh.

Pmx, premaxillary; *n.a*, nasal aperture; *n*, nasal; *l*, lacrymal; *f*, frontal; *i.o.f*, interorbital foramen; *p*, parietal; *so*, supraoccipital; *d*, dentary, *pl*, palatine; *sp*, splenial, *su*, surangular; *a*, angular, *qj*, quadrato-jugal; *cr*, articular; *q*, quadrate; *bo*, basioccipital, *at*, atlas or first cervical vertebra, *ax*, axis or second cervical vertebra; *3 cv-7 cv*, the third to the seventh cervical vertebræ, inclusive

Radio-Active Fertilizers

Scientific farmers will be interested in the account given in the *Chemiker-Zeitung* of the experiments made by Prof. Dr. Julius Stoklasa to determine the influence of radio-active fertilizers upon the growth of plants. These experiments were carried on for a number of years partly under glass, partly in fields set aside for the experiments, and included the use both of natural radio-substances (such as masturan from Joachimsthal, water from the same place, and also water from Brambach and Franzensbad) and of artificial solutions (such as chloride of radium). In his earlier experiments Dr. Stoklasa obtained considerable increase in the size of the plants by using determined and not too strong treatments containing nitrate of uranyl and nitrate of lead. Similar experiments were also made by other investigators with "stimulating" or "catalytic" agents, as they were formerly called. Stoklasa then went systematically to work to investigate the radio-activity and made experiments to determine how the activity of a certain bacillus (*Azotobacter chroococum*), which assimilates elementary nitrogen and converts it into organic forms, is increased by passing radio-active air through its cultural solution. As these investigations yielded positive results he then examined the effect of the emanation upon the higher forms of plant life. It was shown by experiments which were intended to hasten the process of germination that the amount of radio-activity of the water given to the ground in which the experiments were made must vary for different plants, and that to use an unvaryingly fixed strength, in order to obtain an increase of growth, too often resulted in a checking of growth. For example, the amount of non-watery substance gained in one hundred plants was:

	With radio active water.	With water not radio-active.
Pisum arvense	68.73 g.	21.37 g.
Vicia faba	128.87 g.	60.00 g.
Lupinus angustifolius..	37.93 g.	18.45 g.
Hordeum distichum....	90.85 g.	9.08 g.

Of course the decline in the activity, as time went on, of the respective waters was taken into account. During an experiment which lasted 23 days extra increases in non-watery substance of between 62 and 158 per cent were noted in lentils, peas, and wheat. If, though, the water used was too strongly filled with radio-activity 300 to 900 mache units per liter renewed every fourth day—the result was reversed. It can go so far that the leaves become a reddish brown, that is, the chlorophyll is decomposed.

Our investigator found, in particular, in the production of seed that by watering with a radio-water of about 50 to 100 mache units per liter the yield can be increased from 64 to 117 per cent.

Stoklasa also investigated with the aid of glass covers ("emanatoria") the effect of radio-active air upon the development of plants. Using exactly the same soil he surrounded the plants with cylindrical glass-bells into which no emanation was introduced. The result showed that there was a more rapid development of the blossoms in the active air.

These experiments are, therefore, not only most interesting from a scientific point of view, but have also great practical value. Agricultural experiments with radio-active fertilizers have been made before this, but it would seem that the most of such work must still be left for a time to the experimental stations. At the present moment it only pays to use such a fertilizer where the nature of the soil is suitable in itself. Our investigator says further that the radio-active treatment must be adjusted to the nutritive substances of the soil and to the general constituents of vegetation.

An Electrically Driven Warship

As a result of the successful operation of the electric power system in use on the U. S. naval collier "Jupiter," it has been announced by the Navy Department that the same general system will be installed in the new super-dreadnought "California." This will be the first electrically driven warship, and it will have a minimum speed of 21 knots.

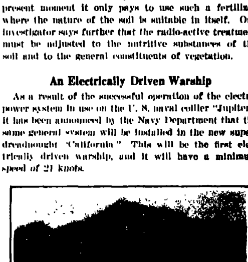

Fig. 5.—A group of cretaceous loons (Hesperornis regalis) as they appeared three or four million years ago. Restoration by Gerhard Heilmann of Copenhagen, and reproduced from a photograph by the author.

Military Surgery

Some Lessons Taught by the Present War

By Our Berlin Correspondent

DR. PAYR the celebrated Leipzig surgeon recently delivered a remarkable lecture before the war correspondents of the Germany army on his personal experience in the field. He has from the very beginning of the war devoted to the military authorities the whole of his time and his exceptional knowledge and in his capacity as General Surgeon to the Saxon army he has been in a position to collect the most valuable experience. In fact his lecture of which an abstract is given in the following may be considered as the most authoritative statement yet made public on the lessons taught by the present war in the field of military surgery.

The learned professor at first cautioned his hearers against the many drawbacks of military surgery. There was primarily the difficulty of watching the course of a given case patients being often lost sight of two or three days after an operation so that the success of the latter cannot always be ascertained. Further there is a risk of the surgeon being hampered in his work by sheer scrupulousness antiseptic conditions being of course far less satisfactory than at home in his own clinic. Another risk finally is the unavoidable rush of work which may induce the surgeon to proceed to operation without mature consideration of actual circumstances.

The projectiles concerned in the case of bullet-wounds are infantry projectiles shrapnel bullets shell fragments bomb fragments and aeroplane arrows. To these should be added dumdum projectiles bullets deflected from their original course and what might be termed indirect projectiles viz. fragments of clothing coins and other objects from the soldier's pockets which have been forced into the wound. The effect of projectiles mainly depends on their percussive force size shape material direction and goal as well as on the number firmness and tension of the organs struck.

The aeroplane arrow is a new weapon which has made its first appearance in the present war. It is a steel rod of the thickness of a pencil with pointed shaft. The rear end is grooved out square so that the point is heavier than the end. As an arrow such as this falls vertically to the ground from a height of say 1,500 meters it will reach a speed of 200 meters per second which is equivalent to the velocity of a rifle bullet. In fact the wounds made by these arrows are very serious.

According to an old classification the lecturer distinguishes several categories of shots. Ricochets when the projectile does not penetrate into the body embedded shots ("Steckschüsse") when the projectile sticks fast in the body and piercing shots ("Durchschüsse") when the projectile pierces the body and comes out at the other end. The degree of harm done to the tissues and organs obviously depends on a number of accessory circumstances. It was thought in former times that blood vessels could bend out of the way of projectiles. However modern infantry projectiles have been found to penetrate right through the vessels even small arteries whose diameter does not exceed that of a quill being pierced. This is why a far greater number of artery lesions have to be dealt with in the present war.

Wounds made by modern projectiles in bones and joints are of especial importance. At short range bones will be shattered into a number of fragments. As the distance increases there is a growing tendency for the projectiles to pierce the bone and just to produce one or two cracks in the neighborhood of the hole. The long tubular bones which are hard as ivory will be split even at very considerable distances say 1,600-1,800 meters whereas bones of a more spongy texture, such as the joint of the knee are pierced smoothly. This is why shots through the joints take a relatively benign course.

The possible effects of shot-wounds are hemorrhage pain shock mutilation and death. As regards pain it is obviously among the foremost duties of the surgeon in war to see that the wounded may as soon as possible get the benefit of alleviating remedies. The general practice now is to administer at the earliest possible moment a morphine injection.

Modern warfare is liable to result in a special abundance of wounds of the head, soldiers on firing from the trenches having to advance their heads. There are two distinct types of head shots viz. on one hand embedded and piercing shots in the case of which the bullet traverses the head directly or sticks fast in the skull or brain and on the other tangential or "groove" shots, when the projectile as it were plows a groove through the skull bone. Tangential shots should be treated differently from embedded and piercing shots bone fragments severed by the bullet producing practically always serious infection.

Most shots through the neck are benign though there are some vital organs concerned blood vessels nerves spinal marrow, and the oesophagus and windpipe. If the windpipe and larynx are affected operation should be proceeded with as promptly as possible thus preventing any risk of stifling.

Shots through the chest are of all shots dealt with in modern warfare those most easily treated. The Japanese used to say that their men in the case of simple breast shots could return to the firing line after a week or so. According to German experience in the present war such patients even in case the lungs have been pierced will at least be transportable after ten to fourteen days. Though they may for some days go on coughing out blood they will in no way be inconvenienced as far as their general condition is concerned. If the heart or aorta has been struck the surgeon's aid of course is of no avail such patients being brought in too late from the battle-field. Whereas in time of peace it is quite feasible to remove a projectile from the heart saving the patient's life by a heart suture any attempt at such an operation in warfare would be futile. As it is modern projectiles are doubtless more humane in their effects than the lead bullets of old and provided the ribs have not been injured the wounded can after quite a short time be restored to full fighting ability.

Shots through the abdomen are an item much discussed in modern war surgery. In time of peace it is an absolute rule to operate as soon as possible by means of a cut through the abdomen thus staying the blood and by opening part of the stomach and the intestines to make the wound inoffensive and prevent any infection liable to result in peritonitis. Already the South African war however has shown such shots to be more benign in case operation is foregone. In fact there are a number of instances in the present war in which good results were obtained by a very simple treatment the patient being kept for a week absolutely quiet and without food or drink. When this limit was not observed the condition of the patient would invariably become worse.

The lecturer next proceeded to answer the question as to how bullet wounds should be treated. According to the best German practice the following principle is adopted. A certain amount of infection should be in any case accounted for which cannot be reduced by any measures whatsoever. If a patient has for instance received a shot through the arm a certain number of microbes have penetrated into the wound which it would be impossible to reduce. Rinsing the wound with water or rubbing it with antiseptics, so far from being of any avail has been found to be harmful the antiseptic liquid diminishing the vital strength of the tissues. However no new noxious agents should be added to those microbes. Experience shows that healthy subjects will deal with a given number of bacteria provided no further germs are allowed to enter the wound. This is the principle controlling the first phase in the treatment of the wounded. The surroundings of the wound are no longer washed and cleaned with soaps as once upon a time but a piece of aseptic gauze is applied to the wound such as is contained in the roll of bandage carried by every German soldier and officer in the field. The first dressing is thus applied which the men themselves or their comrades are trained to do very cleverly.

Another method to prevent the microbes from multiplying is what is termed the arresting process. The parts round the wound are brushed over with tincture of iodine or mastisol. The microbes are fixed by mastix, another advantage of this process is that the aseptic gauze is attached to the wound thus preventing the dressing from being shifted. These methods have given excellent results.

Provision must, of course be made for the wounded to undergo long and difficult transports especially in the case of injury to the bones and joints. Splints have often to be improvised. In fact, the surgeon in time of war, must show much ingenuity in making shift with anything happening to be at hand. The wood of a young tree sticks etc., are, for instance used as splints, but practical splints have also been made from braided straw.

The final treatment of wounds comprises a number of other problems, but a point should be made of avoiding too much zeal. The wound being well dressed and covered with aseptic gauze, there is no need for the whole bandage being exchanged, it being sufficient to renew the outer dressing. Wounds on which the first dressing—made from the man's own dressing materials—had been left, were found after a week to be healed. The greatest care should in any case be used in renewing the bandage, lest any microbes be allowed to penetrate into the wound. Cuts through the windpipe and the tying up of pierced blood vessels should, of course, be made on the very battle-field, whereas the decision as to whether any wounded members should be amputated must be left to the further treatment.

No importance is now attached to the removing of projectiles if the latter cause no inconvenience. This is true of infantry projectiles. According to the lecturer's experience the German steel sleeve projectile, for some unknown reason is more humane than the French copper alloy projectile which frequently causes pain. Shrapnel bullets which are round have far less impact and percussive force than infantry projectiles. Penetrating into the deeper parts of the body, along with such foreign bodies as pieces of clothing etc., they are apt to produce suppuration. In 70 to 75 per cent of shrapnel wounds under treatment suppuration has been observed a slight quantity of chocolate-colored liquid coming out of the wound as this is opened. Shell fragments likewise carry along foreign objects and thus give rise to suppuration, they must therefore be removed.

Artillery wounds which are so frequent in the present war and which by no means take an always benign course are a danger of their own. They give rise to suppuration of the tissues gas phlegmons and tetanus. Good results have in many cases been obtained with the inoculation of a tetanus serum.

Personally the lecturer was able to record a number of striking successes in his surgical practice during the first months of the war. Ordinary shots through the fleshy parts of the members nearly always take a very gratifying course. In many cases the men were restored to fighting ability after a week, though they had only been treated with the dressing material contained in the small parcels carried by each soldier. Infantry bullet shots through joints would take a very benign course if the wound was treated aseptically and if required dressed in splints shortly after the injury.

The effects of aeroplane bombs are very much different from those of bursting shells the injuries even produced by small fragments being so extremely serious as never witnessed by Dr. Payr in the case of shell fragments. Another unpleasant feature of aeroplane bomb fragments is their cutting like knives deep into the members and there piercing the vessels.

Employment of War Prisoners

SIXTY THOUSAND prisoners of war have now been assembled at the Münster camp on the Lüneburg Heath, states *Vorwärts*, where they are cultivating the waste lands. The majority of the men are French, though there is also a number of Belgians Russians and English in the camp. Many previous attempts had been made to cultivate this huge tract of moorland country which is well known to travelers between Hamburg and Berlin but the chronic scarcity of agricultural laborers in peace time had always hindered the project. The local authorities of Hanover accordingly appealed to the military administration to make use of war prisoners for this purpose, and the permission was at once given.

One example may be given (says *Vorwärts*) of the manner in which the work is proceeding. In the district of Neustadt near Hanover the cultivation of the so-called Rodewalder Bruch had long been contemplated. The District Council purchased a large tract of this country which with the help of 2,000 prisoners of war is being broken up and made ready for cultivation. In due course it will be divided up into thirty farm estates. Barracks for the prisoners are being built largely by the aid of the captives themselves, but later on these buildings can be used as cattle sheds and corn stores. The new colony has been christened Lichtenhorst, and if the winter is favorable it is hoped to have the work so far advanced that the first crops can be sown next spring. In this case Hanover will next year have many hundred acres of new land under cultivation with wheat, potatoes, etc.—*London Daily Telegraph.*

An Experiment in Forestry.

THE Laurentide Company of Quebec, producers of pulp and pulpwood, is trying an interesting experiment in reforesting its non-agricultural cut-over lands. It is also importing reindeer from Newfoundland to see if they can take the place of dogs in winter woods work.

Installation of a Gas Engine*

Points to be Observed in Buying, Transporting, Placing and Starting

THERE are a number of points that should be considered before purchasing a gas engine one of which is the amount of power required for the work to be done It is generally advisable no matter what style of engine is to be purchased, to buy a unit somewhat larger than may at first seem necessary It is always well to have some power in reserve because an engine working under an excessive load is inefficient and involves a money loss to the owner on account of the wear and tear on the engine.

The style of engine to be used is determined by the location and the nature of the work to be performed If the engine is used in a fixed location a stationary type should be selected whereas the portable type and the traction engine must be selected when the engine is for use at various points and when loads are to be hauled The selection of the right type is fully as important as the selection of the right make also while attractive paint and a high polish are desirable these tell very little of the real value of the engine

When repairs are necessary the importance of having an engine which has been standardized is fully realized by the purchaser Repair parts should be obtainable at convenient points within a few hours because delays in waiting for repair parts usually prove expensive

It is important to bear in mind that the rated horsepower of an engine is not always a reliable basis for comparison with the actual power that the engine will deliver There are many gas engines on the market rated at five horse-power for example that will hardly have a maximum output of as much as five horse-power under regular operating conditions. Again there are engines built by reputable manufacturers that deliver continually an overload of as much as 20 per cent above their rating If there is any doubt in the mind of the purchaser as to the power that it is possible to obtain from an engine he should insist upon proofs of the actual brake horse-power

When the engine has been purchased the next thing to consider is where it is to be placed In selecting the position for the engine note that it ought to be placed in the cleanest driest and lightest spot obtainable If it is to be belted to machinery that is already in place it is necessary to decide where the flywheel will be located and the foundation should be made with this in mind If the machinery is to be installed later, suitable position for it must be determined at the time the engine is installed in order to insure that no difficulties will be met with in transmitting the power If the engine is installed in a large room a small room or space should be partitioned off around it in order to keep out dust and dirt. Under all circumstances, never allow a gas engine or any other engine for that matter to run in the same room with emery or polishing wheels

Assuming the engine to be of the stationary type the purchaser should obtain a templet and anchor bolts generally furnished with each engine The templet is a wooden frame of the size of the bottom of the base of the engine having holes in it to match the holes in the base of the engine frame

THE FOUNDATION

The dimensions of the foundation at the bottom should be at least twice the length of the engine base and not less than two and one half times the width and the depth of the foundation should be equal to its length The shape of the foundation is then made in the form of a frustum of a pyramid sloping up toward the top where it is only about three inches larger on all sides than the base of the engine When the hole has been dug in the ground a form for the concrete must be made and then the concrete is mixed as follows one sack of good cement, two wheelbarrows of sand and three wheelbarrows of crushed rock or small gravel well mixed with water to make it easy to handle When putting the concrete into the form it is advisable to use old scrap iron of all kinds chains wire etc to reinforce the concrete and keep it from cracking Put in the concrete and scrap iron together, tamping it tightly into the form Before putting in the concrete however place the anchor bolts in the bottom of the hole, with large heavy washers on their heads, and use the templet to locate them properly at the bottom then run the nuts down on the anchor bolts far enough to allow the templet to rest upon them while locating the bolts at the top at about the level where the engine will be set on the foundation Then fasten the bolts in some way so that they will not move while the concrete is being put in place The wooden templet is left on the top of the foundation, the nuts, of course, being removed when the foundation reaches them and the engine is set on the top of the templet as it is advisable to use a thin strip of wood between the concrete and the cast iron of the base The foundation should be left to set at least four days before the engine is placed on it

REMOVING AN ENGINE FROM A RAILROAD CAR

The foundation now being ready we will assume that the engine has arrived in a railroad car at the station and that it is to be removed from there by the purchaser A few points relating to this operation will prove of value The engine has been delivered to the transportation company by the manufacturer or dealer properly packed for shipment. The responsibility of the manufacturer or agent stops at this point and the transportation company is supposed to deliver it to the purchaser in perfect condition The engine if of a heavy type has been transported in a separate car and is left on a side track accessible for teams The first thing to do is to have the local station agent make an inspection of the engine in the presence of the purchaser or his representative to see if it is in good condition and that no damage has been done to it in transportation Should any damage be revealed at this inspection the station agent should be required to make a notation of the damage upon the expense bill before the freight is paid After this is done the transportation company is liable for the damage if any and the buyer is safe in unloading and taking charge of the engine

If any timbers or assistance are needed in unloading the engine from the car the transportation company through its agent is supposed to furnish them If the transportation company furnishes bad timbers for this purpose and an accident is caused thereby the mere acceptance by the purchaser of the bad timbers does not place the responsibility upon him The engine should preferably be moved onto a flat top dray wagon without springs In moving the engine take care to see that it is properly supported at all times and see where each step in the moving is going to leave it If any accident happens to the engine before it is clear of the car or before it is taken off the skids conveying it from the car to the wagon the transportation company is liable for the damage because being a local shipment the company is supposed to remove it from the car and the purchaser is merely acting for the company when taking the engine from the car After the engine is placed on the wagon the purchaser is entirely responsible for it.

As an example of what may be encountered in unloading an engine the following experience may be mentioned An engine arrived at its destination in good condition and the car was set on a siding near a pile of ties that were to be used in unloading Some other timbers were also necessary which the agent of the railroad company furnished but these were not as strong as the man unloading the engine required however the station agent informed him that he would have to use them He went on with the operations taking extra precautions to brace the weak timbers but just as the engine was about half way between the car and the wagon one of them gave way and the engine went into a ditch upside down The man in charge of the unloading went to the long distance telephone and called up the general agent of the manufacturing company stating the circumstances and asking for instructions He was told to inform the station agent that the engine could not be used and that it would be left on the railroad company's hands A new engine was loaded at the factory the same day and shipped and in that case ample assistance was rendered in unloading the new engine The first engine was loaded by the railroad company onto a car and returned to the factory free of charge the bill for the necessary repairs was rendered to the railroad company and was paid with out a damage suit.

After the engine is safely placed on the wagon it should be conveyed by the safest and easiest road to the place of installation Avoid uneven ground and bad street crossings take plenty of time and be sure of every move Always release the team from the wagon while loading and unloading the engine. The unloading is greatly simplified if two trenches are dug for the wheels of the wagon so that the axles almost touch the ground In this case the timbers on which the engine is handled will be more nearly level. If they are entirely level rollers may be used under the skids to which the engine is fastened If however the timbers slope at all rollers should not be used The main thing is to avoid haste, and not to permit anything to interfere until the engine has been placed on the foundation

INSTALLATION OF AUXILIARIES

The next thing is to select a suitable place for the battery box This place should be dry and free from vibration The wiring is now connected If natural gas is to be used as a fuel it is necessary to have a special mixer which will be furnished by the manufacturer of the engine All that is necessary is a gas bag or tank and piping to allow the charge to be drawn quickly into the cylinder Some engines use gasoline for a start and then switch onto the natural gas while others start directly on the gas If the engine will start on the gas there is no reason for using gasoline

If liquid fuel is to be used it is advisable to place the fuel tank outside the building and it is still better to bury it in the ground After the tank has been buried in a suitable place it is an easy matter to arrange the piping to the fuel pump on the engine As far as possible this piping should be underground as it is out of the way A pipe for the fuel passing from the pump to the mixer and a pipe for the overflow to return from the mixer bowl to the tank must be provided If the overflow pipe stops at the top of the fuel tank it will not be necessary to have a vent hole at the top of the tank as the air will flow into the tank from the overhead pipe which will not always be full of gasoline The pump pipe should pass to the bottom of the tank and should be provided with a light screen to prevent foreign substances from passing into the mixer

STARTING A NEW ENGINE

After the engine is properly installed the first thing is to start it running This is done by turning on the battery switch setting the needle valve in the starting position turning off the air damper releasing the compression and giving the flywheel a few turns which will put it in motion After the engine has made a few revolutions open the air damper close the needle valve to the running position put the relief cam back into place and let the engine run watching for developments It is of course presumed that all the oilers and grease cups have been filled and that all movable parts have been oiled with the oil can Now see that water enters the cylinder cooling jacket within five minutes or stop the engine as it is not safe to allow it to run without cooling water on the jacket It is best to allow the engine to run an hour or so without any load and to watch the bearings to see that they do not become overheated In case of doubt on any point stop the engine and examine it

In cold weather a gasoline engine is more difficult to start than in warm weather the reason being that gasoline in changing from a liquid to a vapor reduces its temperature about 50 deg Fahr If the air is cold on the outside of the cylinder and the mixer has taken in vapor 30 degrees colder it is easy to understand that this would interfere with the proper vaporization Hence it will be difficult to start the engine There are several methods of overcoming this difficulty either by warming the gasoline warming the air or by using one part ether and four parts gasoline for a start this will make a liquid that will vaporize readily several degrees below zero To warm the gasoline is a process which is dangerous and should only be attempted as a last resort. It can be done safely only by using hot water or a hot cloth The air may be warmed by heating a piece of iron red hot and holding it at the mouth of the intake pipe allowing the air to pass over it as it goes into the intake pipe after which it joins the gasoline vapor and heats it.

* Reprinted from *Machinery* From an article prepared mainly from notes by J. L. Hobbs, gas engine expert.

Motor Fuel in Germany

A very large proportion of the supplies of gasoline used by motor cars in Germany has been obtained from the United States as well as considerable quantities from Russia, and the East Indies It is believed that these sources of supply have now been effectively cut off, so that outside of accumulated stock the wells of Gallacia are the only ones from which fuel supplies of this class can be obtained and these wells can be depended on for little more than crude oils and these in no great quantities It is reported that alcohol and benzol are used exclusively by the cars in the military service, but the supply of alcohol must be limited, as the grain, potatoes etc, from which it is made will undoubtedly soon be required for food purposes and it is doubtful if the supplies of benzol are anywhere near sufficient In a machine-made war such as the present one pre-eminently is the question of a supply of motor fuel is a most important item, and it will be interesting to see how Germany will solve the problem.

A Great Railway Electrification Project

440 Miles of the Chicago, Milwaukee & St. Paul Mountain Lines to be Operated by Electric Power

The Chicago, Milwaukee & St Paul Railroad has decided to electrify four engine divisions of its Puget Sound lines, extending from Harlowton Montana, to Avery, Idaho, a total distance of about 440 miles, aggregating approximately 650 miles of track, including yards and sidings.

Work has already been started on the first engine division, consisting of 113 miles of main line track between Three Forks and Deer Lodge, Montana and contracts have been let to the General Electric Company for the electric locomotives, substation apparatus and line material. Power will be secured from the Montana Power Company, which will also construct the transmission and trolley lines.

While the four engine divisions of 440 miles comprise the extent of track to be equipped in the near future, it is understood that plans are being made to extend the electrification from Harlowton to the coast, a distance of 850 miles, should the operating results of the initial installation prove as satisfactory as anticipated.

The plans of the Chicago, Milwaukee & St Paul Railway are of especial interest, as this is the first attempt to install and operate electric locomotives on tracks extending over several engine divisions, under which condition it is claimed the full advantage of electrification can be secured. The various terminal and tunnel installations have been made necessary, more or less by reason of local conditions; but the electrification of this road is undertaken purely on economic grounds with the expectation that superior operating results with electric locomotives will effect a sufficient reduction in the present cost of steam operation to return an attractive percentage on the large investment required. If the anticipated savings are realized in the electric operation of the road this initial installation will constitute one of the most important milestones in electric railway progress, and it should foreshadow large future developments in heavy steam road electrification. The success of electric operation on such a large scale will, at least, settle the engineering and economic questions that enter into the advisability of making such an installation, and will limit similar future problems to the means of raising the money expenditure required.

The first step taken toward electrification by the Chicago, Milwaukee & St. Paul Railway was to enter into a contract with the Montana Power Company for an adequate supply of power over the 440 miles of main line considered for immediate electrification. The precautions taken, both by the railway company and power company, to safeguard the continuity of power supply should guarantee a reliable source of power subject to few interruptions of a momentary nature only.

The Montana Power Company covers a great part of Montana and part of Idaho with its network of transmission lines, which are fed from a number of sources of which the principal ones are tabulated below:

Madison River	11,000 kilowatts
Canyon Ferry	7,500 kilowatts
Hauser Lake	14,000 kilowatts
Big Hole	3,000 kilowatts
Butte, steam turbine	5,000 kilowatts
Rainbow Falls	21,000 kilowatts
Small powers aggregating	7,390 kilowatts
Total power developed	68,890 kilowatts

Further developments, part of which are under construction, are as follows:

Great Falls	85,000 kilowatts
Holter	30,000 kilowatts
Thompson Falls	30,000 kilowatts
Snake River	20,000 kilowatts
Missoula River	10,000 kilowatts
Total	175,000 kilowatts
Total power capacity, developed and undeveloped	244,000 kilowatts

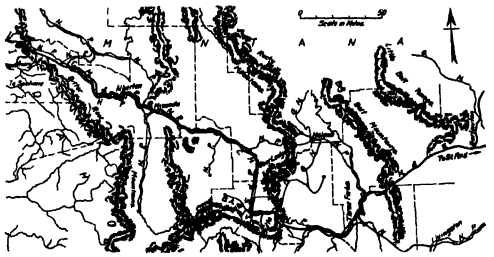
The several power sites are interconnected by transmission lines supported on wooden poles and operating at 50,000 volts for the earlier installations, and on steel towers and operating at 100,000 volts for later installations. Ample water storage capacity is provided in the Hobgen reservoir of 300,000 acre feet, supplemented by an auxiliary reservoir capacity at the several power sites, which brings the total up to 418,000 acre feet. The Hobgen reservoir is so located at the head waters of the Madison River that water drawn from it can supply in turn the several installations on the Madison and Missouri rivers, so that the same storage capacity is used a number of times, affording an available storage capacity considerably greater than is indicated by the figures given. It would seem, therefore, in changing from coal to electricity as a source of motive power, that the railroad is amply protected in respect to the reliability and continuity of the power supply.

Due to the great facilities available and the low cost of construction under the favorable conditions existing, the railway company will purchase power at a contract rate of 0.00536 cent per kilowatt-hour, based on a 60 per cent load factor. It is expected, under these conditions, that the cost of power for locomotives will be considerably less than is now expended for coal. The contract between the railway and power companies provides that the total electrification between Harlowton and Avery, comprising four engine divisions, will be in operation January 1st, 1916.

In order to connect the substations with the several feeding-in points of the Montana power transmission lines, a tie-in transmission line is being built by the railway company that will permit feeding each substation from two directions and from two or more sources of power. This transmission line will be constructed with wooden poles, suspension type insulators, will operate at 100,000 volts, and will follow, in general, the right of way of the railway company except where advantage can be taken of a shorter route over public domain to avoid the necessarily circuitous line of the railway in the mountain districts.

The immediate electrification of 113 miles will include four substations containing step-down transformers and motor generator sets with necessary controlling switchboard apparatus to convert 100,000-volt, 60-cycle, three-phase power to 3,000 volts direct current. This is the first direct current installation using such a high potential as 3,000 volts, and this system was adopted in preference to all others after a careful investigation extending over two years. The 2,400-volt direct current installation of the Butte, Anaconda & Pacific Railway in the immediate territory of the proposed Chicago, Milwaukee & St. Paul electrification has furnished an excellent demonstration of high-voltage, direct-current locomotive operation during the past year and a half, and the selection of 3,000 volts direct current for the Chicago, Milwaukee & St Paul was due, in a large measure, to the entirely satisfactory performance of the Butte, Anaconda & Pacific installation.

The equipment for this road was also furnished by the General Electric Company, and a comparison based on six months' steam and electric operation shows a total net saving of more than 20 per cent on the investment or total cost of the electrification. These figures, of course, do not take into account the increased capacity of the lines, improvement to the service, and the more regular working hours for the crews. The comparison also shows that the tonnage per train has been increased by 35 per cent, while the number of trains has been decreased by 25 per cent, with a saving of 27 per cent in the time required per trip.



Map of the mountain country of Montana where the Chicago, Milwaukee and St. Paul Railroad proposes to use electric power to haul its trains.

SUBSTATIONS.

The substation sites of the Chicago, Milwaukee & St. Paul electrified zone provide for an average intervening distance of approximately 35 miles, notwithstanding that the first installation embraces 20.8 miles of 2 per cent grade westbound and 10.4 miles of 1.66 per cent grade eastbound over the main range of the Rocky Mountains. With this extreme distance between substations and considering the heavy traffic and small amount of feeder copper to be installed, it becomes apparent that such a high potential as 3,000 volts direct current permits of a minimum investment in substation apparatus and considerable latitude as to location sites.

The substations will be of the indoor type, transformers being three-phase, oil-cooled, and reducing from 100,000 volts primary to 2,300 volts secondary, at which potential the synchronous motors will operate. The transformers will be rated 1,800 and 2,500 kilovolt-amperes and will be provided with four 2½ per cent taps in the primary and 50 per cent starting taps in the secondary.

The motor generator sets will comprise a 60-cycle synchronous motor driving two 1,500-volt, direct-current generators connected permanently in series for 3,000 volts. The fields of both the synchronous motor and direct current generators will be separately excited by small generators direct connected to each end of the motor-generator shaft. The direct-current generators will be compound wound, will maintain constant potential up to 150 per cent load, and will have a capacity

SCENES IN THE REGION IN WHICH THE CHICAGO MILWAUKEE AND ST PAUL RAILROAD WILL USE ELECTRIC POWER

for momentary overloads up to three times their normal rating To insure good commutation on these overloads, the generators are equipped with commutating poles and compensating pole-face windings The synchronous motors will also be utilized as synchronous condensers, and it is expected that the transmission line voltage can be so regulated thereby as to eliminate any effect of the fluctuating railway load

The location and equipment of the several substations is as follows

Station	Miles from Deer Lodge	No of units	Kw per unit	Total
Morel	17 1	2	2 000	4 000
Janney	50 5	3	1 500	4 500
Piedmont	77 9	3	1 500	4 500
Eustis	120 6	2	2 000	4 000

OVERHEAD CONSTRUCTION

The trolley construction will be of the catenary type in which a 4/0 trolley wire is flexibly suspended from a steel catenary supported on wooden poles the construction being bracket wherever track alignment will permit and cross span on the sharper curves and in yards Steel supports instead of wooden poles will be used in yards where the number of tracks to be spanned exceeds the possibilities of wooden pole construction Poles for the first installation are already on the ground and thirty miles of poles are set. Work in this direction will be pushed with all speed and will be completed in the summer of 1915 ready for operation in the fall on the delivery of the first locomotives

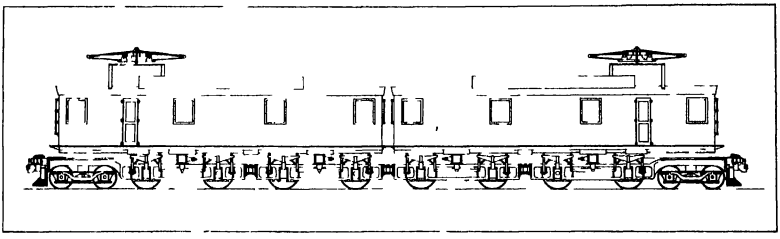
As the result of careful investigation and experiments a novel construction of trolley will be installed composed of the so called twin conductor trolley This comprises two 4/0 wires suspended side by side from the same catenary by independent hangers alternately connected to each trolley wire This form of construction permits the collection of very heavy current by reason of the twin contact of the pantograph with the two trolley wires and also insures sparkless collection under the extremes of either heavy current at low speed or more moderate current at very high speeds. It seems that the twin-conductor type of construction is equally adapted to the heavy grades calling for the collection of very heavy currents and on the more level portions of the profile where maximum speeds of 60 miles per hour will be realized with the passenger trains having a total weight of over 1000 tons The advantage of this type of construction is due partly to the greater surface for the collection of current but largely to the very great flexibility of the alternately suspended trolley wires a form of construction which eliminates any tendency to flash at the hangers either at low or high speed Including sidings passing and yard tracks, the 113 miles of route mileage is increased to approximately 168 miles of single track to be equipped between Deer Lodge and Three Forks in the initial installation

LOCOMOTIVES

The locomotives to be manufactured by the General Electric Company are of especial interest for many reasons They are the first locomotives to be constructed for railroad service with direct current motors designed for so high a potential as 3000 volts They will weigh approximately 260 tons and will have a continuous capacity greater than any steam or electric locomotive yet constructed Perhaps the most interesting part of the equipment is the control which is arranged to effect regenerative electric braking on down grades This feature has yet has never been accomplished with direct-current motors on so large a scale The general characteristics as proposed are tabulated below

Total weight	260 tons
Weight on drivers	200 tons
Weight on each guiding truck	30 tons
Number of driving axles	8
Number of motors	8
Number of guiding trucks	2
Number of axles per guiding truck	2
Total length of locomotive	112 feet
Rigid wheel base	10 feet
Voltage of locomotive	3,000
Voltage per motor	1,500
Horse-power rating 1 hour each motor	430
Horse-power rating continuous each motor	375
Horse power rating 1 hour complete locomotive	3 440
Horse power rating continuous complete locomotive	3 000
Trailing load capacity 2 per cent grade	1 250 tons
Trailing load capacity 1 per cent grade	2 500 tons
Approximate speed at these loads and grades	16 m p h

The Chicago Milwaukee & St Paul Railway from Harlowton to the coast crosses four mountain ranges The Belt Mountains at an elevation of 5 768 feet the Rocky Mountains at an elevation of 6,350 feet the Bitter Root Mountains at an elevation of 4 200 feet and the Cascade Mountains at an elevation of 3 010 feet The first electrification between Three Forks and Deer Lodge calls for locomotive operation over 20 8 miles of 2 per cent grade between Piedmont and Donald at the crest of the main Rocky Mountain Divide so that 2 per cent ruling grades on the west and east slopes of the Rocky Mountain Divide with the help of a second similar freight locomotive acting as a pusher. Track provision is being made at Donald, the summit of the grade, to enable the pusher locomotive to run around the train and be coupled to the head end to permit electric braking on the down grade In this case, the entire train will be under compression and held back by the two locomotives at this head end, the entire electric braking of the two locomotives being under the control of the motorman in the operating cab of the leading locomotive It is considered that electric braking will prove very valuable in this mountain railroading for in addition to providing the greatest safety in operation it also returns a considerable amount of energy to the substations and transmission system, which can be utilized by other trains demanding power. In this connection the electric locomotives will have electric braking capacity sufficient to hold back the entire train on down grade leaving the air brake equipment with which they are also equipped to be used only in emergency and when stopping the train There is therefore provided a duplicate braking system on down grades which should be reflected in the greatest safety of operation afforded and the elimination of a considerable part of break downs wheel and track wear



3 000 volt direct current electric locomotive Most powerful yet built

the locomotives will be fully tested out as to their capacity and general service performance in overcoming the natural obstacles of the first engine division

The initial contract calls for nine freight and three passenger locomotives having the above characteristics and similar in all respects except that the passenger locomotives will be provided with a gear ratio permitting the operation of 800-ton trailing passenger trains at approximately 60 miles per hour and will furthermore be equipped with an oil fired steam heating outfit for the trailing cars The interchangeability of all electrical and mechanical parts of the freight and passenger electric locomotives is considered to be of very great importance from the standpoint of operation and maintenance

The cab consists of two similar sections extending practically the full length of the locomotive Each section is approximately 52 feet long and the cab roof is about 14 feet above the rail exclusive of the housings for ventilation The trolley bases are about 5 feet above the roof owing to the unusual height of the trolley wire which will be located at a maximum elevation of 25 feet above the rail The outer end of each cab will contain a compartment for the engineer while the remainder is occupied by the electric control equipment, train heater air brake apparatus etc

MOTORS

The eight motors for the complete locomotive will be type G E 253 A This motor has a normal one-hour rating of 430 horse-power with a continuous rating of 375 horse-power The eight motors will thus give the locomotive a one-hour rating of 3 440 horse-power and a continuous rating of 3 000 horse-power which makes it more powerful than any steam or electric locomotive ever built. The drawbar pull available for starting trains will approximate 120 000 pounds at 30 per cent coefficient of adhesion

Each motor will be twin-geared to its driving axle in the same manner as on the Butte, Anaconda & Pacific, the Detroit River Tunnel and the Baltimore & Ohio locomotives a pinion being mounted on each end of the armature shaft The motor is of the commutating pole type and has openings for forced ventilation from a motor-driven blower located in the cab

The freight locomotives are designed to haul a 2,500-ton trailing load on all gradients up to 1 per cent at a speed of approximately 16 miles per hour, and this same trainload unbroken will be carried over 1.66 and and overheating with consequent reduction in maintenance and improvement in track conditions

With the completion of the remaining engine divisions it is proposed to take advantage of the possibilities afforded by the introduction of the electric locomotive by combining the present four steam engine divisions into two locomotive divisions of approximately 220 miles length changing crews however at the present division points As the electric locomotive needs inspection only after a run of approximately 2 000 miles requires no stops for taking on coal or water or layover due to dumping ashes cleaning boilers or petty round house repairs it is expected that the greater flexibility of the locomotive so provided will result in considerable change in the method of handling trains now limited by the restrictions of the steam engine

The electrification of the Chicago Milwaukee & St. Paul is under the direction of Mr C A Goodnow, assistant to the president and in charge of construction. The field work is under the charge of Mr R Beeuwkes electrical engineer for the railway company

Handling Freight by Motor Trucks

A FEW years ago an innovation appeared in the way of a motor-driven truck for handling baggage in a few large railway passenger stations, and since that time great progress has been made in adapting the system to the handling of freight, with the result that the cost has been very considerably reduced An instance illustrating the advantage gained is the report of the experience of the Central Georgia Railroad in handling cotton between the piers and storehouses at Savannah, where by the old methods of hand labor the cost was a little over six cents per bale, which the electric trucks driven by storage batteries reduced to about two and one third cents Portable motor-driven jib crane loaders were then added, and these brought the cost, including fixed charges, maintenance and cost of power, to about 2 2 cents per bale This is a remarkable showing in view of the fact that the electric outfit is in use only about four months each year By the use of the loader the trucks can be loaded at the rate of a 500-pound bale every twelve seconds, which is much quicker than hand loading, and can be kept up all day which is not the case with hand labor Besides the money saving effected by the use of electric power there is an additional saving in time.

Arithmetical Machines—I*

Their History, Theory and Methods of Construction

By H. L. Goldberg, M. W. S. E.

The first arithmetical machine was invented, as far as I know, by Blaise Pascal, about 1641. Pascal, you will recall, was the wonderful Frenchman who at the age of sixteen, discovered the theorem in conic sections called Pascal's hexagram. He was not only one of the foremost mathematicians of his day but also excelled in mechanics. At the age of 19 he produced the first machine with mechanical means for the carrying of the tens. Immediately the field of calculating machines became fertile ground and many inventors cultivated it.

The next notable production was by Leibnitz about 1671. He built several multiplying and dividing machines, and a good description of one constructed about 1700—the first in which a multiplicand could be set up and preserved during the process of multiplication—is available. But this machine was never put on the market. In some of its features it resembled the Thomas machine of later years, which was a well designed and well-constructed multiplying and dividing machine built by Thomas and marketed in Europe about 1820 and which is still in use.

Up to that time inventors had been modest and were satisfied with making simply multiplying and dividing machines, but about 1825 Charles Babbage of England became bolder and built a difference engine. Let me recall to you that the series of integral values of any rational algebraic polynomial can be calculated by the method of differences. This is shown in algebra. It is true that many other functions, for instance logarithms, can be calculated by the same method of differences. The method will not apply throughout the whole series of logarithms, but does apply with sufficient accuracy for a group of a large number of consecutive terms. Thereafter a new start is made for another group. Babbage invented his machine intending originally to apply it to the calculation of logarithms as well as to the calculation of all sorts of nautical and astronomical tables. When he was about half through with his first or difference machine he decided that it was not good enough, and invented what he called the analytical engine—a calculating machine that could compute any arithmetical results that could be computed by a human being. For instance, it would extract square root, cube root, solve equations by Horner's process, and so on. However, this machine was never built. The principle on which it depended was similar to that of the Jacquard loom. Many of you have doubtless seen a machine, controlled by a series of cards pierced with holes, which weaves a portrait, say of George Washington. Babbage proposed to juggle with numbers in the same manner as the Jacquard loom juggles with threads. It was a most ambitious project, but was not fulfilled. I have read his book and studied some of his mechanisms. They are not as simple as they might be. Babbage claims, incidentally, that to meet the necessities of his work, he was the first to graduate the screws of the slide rests of his lathes. He spent a considerable sum of money advanced him by the government of England, as well as his own fortune, without completing any machine.

Another commercial advance we find in about 1878, when the Russian Ohdner put on the market the machine that is now called the Brunsviga, and is also marketed under the names of the Marchand, the Thales, the Triumphator, the Teitgen, etc.

In this country I believe the first patent on calculating machines issued by the Patent Office was to O. L. Castle of Alton, Ill., about 1850. It was for a ten key adding machine which did not print. It added in only one decimal column, helping a bookkeeper to add up, say, the units column of a long account. It could then be used for the tens, and so on. We find quite early key machines having a keyboard like the present Burroughs keyboard, namely 81 keys. Riggs in America shows such a machine about 1854. It is astounding how early some ambitious projects were launched. For instance, in 1871 we find that Teasdale invented a machine for multiplication. Suppose it were desired to multiply 4892 by 7926. Put the multiplicand and multiplier in the machine, turn the crank, and presto, there is your answer! No such machine has yet been put on the market, although attempts have been made in that direction. About 1888 the first Burroughs machine which both added and printed appeared on the market. It was quite unlike the present type, which dates from about 1893. In 1888 we find the first typewriter attachment invented by Ludlum. The Duplex Comptometer invented by Dorr E. Felt was put on the market about eight years ago.

Many patents on calculating machines have been issued by the Patent Office, and under the circumstances it will therefore be impossible for me to refer to any more than a few of the mechanisms described. Moreover, for the purpose of convenience, the sketches which I have made are diagrammatic and follow no particular machine.

Adding Machines.—Our system of numeration is a decimal system. We count in cycles of ten. After reaching ten we start again to twenty, then to thirty, and so on. Of course we have exceptions, namely eleven, twelve, and thirteen. Logically, however, we should say ten-one, ten-two, and ten-three. While we are able to twist ourselves and our minds into all sorts of knots, mechanism refuses to be so accommodating, and in a decimal mechanism eleven is always ten one and nothing else. We find that almost all arithmetical machines represent the number by mechanical cycles corresponding to ten, namely, totalizer wheels, each provided with teeth some multiple of ten, for instance, the wheels have ten teeth, twenty teeth, thirty teeth, etc. (Let me state here that arithmetical machines calculating with Arabic numerals have been made without the numbers being represented on wheels. In fact, one machine, Mr. Brickens, has no wheels whatever.) In totalizers where the number is supposed to be read off by the operator, it is customary to supply the wheels with the digits 0, 1, 2, 3, 4, 5, 6, 7, 8 and 9. In machines where the number on the wheels is not read by the operator, the digits are not supplied. For instance, the Burroughs has digits on its totalizer, while the Dalton has not.

What means are used in putting a number into an arithmetical machine?

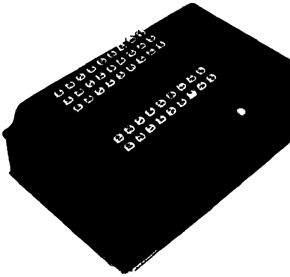
Some machines, for instance the Triumph, are nothing but big totalizers; the totalizer wheels are so large that the operator has room enough to place his fingers through a window into the spaces between the teeth of the wheels. The machine is furnished with dials indicating where the operator is to place his finger for a 1, for a 2, etc. After properly locating the finger, the operator pulls it down as far as it will go, that is, until he strikes the bottom of the window. He thus rotates the engaged totalizer wheel one step, two steps, or any number that he desires. This is certainly the most direct method, and was the one used by Pascal in 1641. Certain miniature machines working on the same principle have been built, but instead of using the finger, a pencil or sharp steel point, called a stylus, is placed through the window between the teeth of the wheels.

Let us put the number 132 into the machine. We place the finger in the 1 location of the hundreds wheel and pull down. We then put the finger in the 3 place of the tens wheel and pull down. And so on. The capacity of the machine is of course determined by the number of totalizer wheels, of which I have represented only two.

Carrying Mechanism.—Each totalizer wheel is supplied somewhere on its circumference with a variation which mechanically determines the location of the carrying point and which arithmetically corresponds to the 0. The first step away from the 0 is 1, both mechanically and arithmetically, the second step 2, and so on. This variation on the totalizer wheel is ordinarily a projection like a pin, as in the Wahl, the Burroughs, the Brunsviga and other machines. On the other hand, it may be instead a drop or fall or a cut, as in the Howieson and other machines. Of the various carrying mechanisms possible I will now explain the principle of the one illustrated in Figs. 1 and 2. Something similar is used in the Wahl machine.

In the totalizer there are two sets of gears, the totalizer gears proper T and the intermediate wheels B. Each totalizer wheel has, as shown in Fig. 1, forty teeth and a projection P to the left for each ten teeth. The number of teeth upon the intermediate wheels is of no importance. If one of the wheels T be rotated, then in due time its carrying projection P will engage

Brunsviga machine



Comptometer

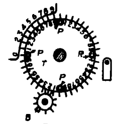


Fig. 1

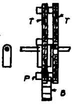

Fig. 2

* A paper read before the Western Society of Engineers, and published in the Journal of the Society.

the co-operating wheel *B*, which will be turned, and which will thus turn one step the next higher wheel *T* to the left.

Let us mentally add the numbers 132 and 654. (Fig. 3, Ex. 1.) We start from the units and say 2 and 4 are 6; 3 and 5 are 8; 1 and 6 are 7. The answer is 786. In this particular example no carrying of the tens occurred. The process that did occur seems to have no universally accepted name, and I will term it accumulation. Take another example. (Fig. 3, Ex. 2.) Add 9999 and 1. Again starting from the units decimal place, we say 9 and 1 are 10, put down 0 and carry 1. We then go on, and in the tens decimal place say 9 and the carried 1 are 10; put 0 down and carry 1. In the hundreds again, 9 and the carried 1 are 10; put down 0, carry 1; and so on to the end, where we put down the last carried 1. The addition of the numbers 9999 and 1 requires practically nothing but tens-carrying. Let us take still another example. (Fig. 3, Ex. 3.) Let the two numbers to be added be 9999 and 9999. We say in the units place, 9 and 9 are 18; put down 8, carry 1; and so on. We see that in every decimal place from the units on there occur both accumulation and carrying. No new process is discovered. It will be found that addition is composed of only these two, namely, accumulation and carrying. Let us refer again to the third example. In the units place we say, 9 and 9 are 18; put down 8 and carry 1. In the tens place we say, 9 and 9 and the carried 1 are 19; put down 9 and carry 1; and so on to the end. Let me call to your attention that in this process we first accumulate, then tens-carry, then again accumulate, then again tens-carry, and so alternate one with the other to the end. That is, both the accumulation and the carrying are successive; each follows the other, and only one is done at a time.

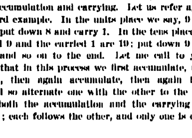

FIG. 3

On account of the limitation of the human mind, we in school are taught to add by doing one thing at a time. In addition as shown above, we accumulate and tens-carry singly and successively. The Wahl totalizer, however, is not so limited. It carries in all the decimal places simultaneously, but accumulates in only one decimal place at one time, that is, successively.

Now consider the third example from the standpoint of this totalizer. The totalizer is supposed to have already absorbed the first number, 9999, and the following description of the operation deals with the process of absorbing and digesting the second number:

First, the totalizer receives (as before described) the 9 of the thousands place. This immediately mixes with the contents already in its stomach; namely, the first number. The bite is simultaneously digested, and the result is 18999. A second bite is taken, and digested during the swallowing. The result is 19899. The 9 in the tens place is swallowed, and the result is 19989; and when the last 9 has been absorbed the result is immediately 19998. In the second example it would make one bite of the 1 in the units place, carry simultaneously throughout all its decimal places, and be completely done.

Machines whose totalizers act as just described are found among the typewriter attachments, of which the Underwood Computer as well as the Wahl are examples. The first typewriter attachment patented by Ludlum in 1888 operated in the same manner.

Locking Mechanism. The above is the principle of the carrying mechanism. In practice, many additional features are supplied, some of which I will point out. The quick movement of a wheel *T* will cause its projection *P* to strike the intermediate wheel *B* quite sharply, which thereupon will rotate the next higher wheel *T*, not only one step, as required, but perhaps several superfluous steps. A mistake will thus be made. To prevent such mistakes, locking mechanism is introduced. In the Wahl machine the locking mechanism is composed of Geneva gearing. This locking Geneva gearing in its turn requires unlocking mechanism, so that the final result is far more involved than the above sketch indicates. In the Underwood-Wright machine, which uses a similar carrying mechanism, overthrow is prevented by a set of spring pawls. These check the momentum of the flying wheels, but, of course, they also interpose a resistance against the free starting of the wheels, which in turn leads to motor mechanism to drive them.

You will notice that the above carrying mechanism is reversible. It will work just as well if the wheels *T* are rotated one way as the other. It, therefore, can be and is used for both addition and subtraction, subtraction being accomplished by rotating the gears *T* in the direction opposite to that for addition.

Figs. 1 and 2 show only two wheels *T* and only one wheel *B*. In practice there are totalizers with up to twenty wheels *T* and, therefore, nineteen wheels *B*. Please note that in order to function correctly, only one wheel *T* at a time can be used for the insertion of the number. Pulling all four wheels down at once to add 9999 to 9999, would result in a mistake. This is

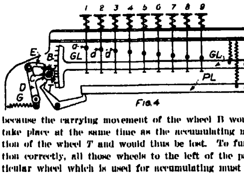

FIG. 4

because the carrying movement of the wheel B would take place at the same time as the accumulating motion of the wheel *T* and would thus be lost. To function correctly, all those wheels to the left of the particular wheel which is used for accumulating must be held in reserve in order to properly carry the tens. All the wheels to the right must be held non-interfering. Any carrying that does take place is, however, theoretically transmitted simultaneously throughout all the higher wheels to the left, and not successively as in the carrying mechanism to be described. The totalizer accumulates successively, but carries simultaneously.

Keys. When we come to the subject of keys, we find two distinct and contending camps. There are what are called the 81-key machines and there are the so-called 10-key machines.

The keyboard of the 81-key machine is supplied with a number of banks of keys, say nine, each containing the keys 1, 2, 3, 4, 5, 6, 7, 8, and 9. There is a bank for the units decimal place, another bank for the tens, and so on. Notice that the zeros do not occur at all. In using such a machine the operator places his finger on the proper key in the proper decimal place, and pushes. For the number 1085 he places his finger on the 1 key of the thousands bank, on no key in the hundreds bank, on the 8 key in the tens bank, and on the 5 key of the units bank. He might operate with only one finger or with all the fingers; with the fingers one at a time or all together. Operators become expert on these machines, and I have seen them use sometimes the highest figure first and units last; again, units first and the highest figure last; and sometimes a mixed order. Among the machines that have 81 keys are the Burroughs, the Comptometer, the Comptograph, the Ensign, the Wales, etc.

The 10-key machines have no sets of banks of keys, but are provided with only one set of 10 keys; namely, 0, 1, 2, 3, 4, 5, 6, 7, 8, and 9, and this set of keys is used for *all* decimal places. Here the 0 must be used. In writing a number like 11, the 1 key is struck twice. In writing 101, the operator would strike, in order, the 1, the 0, and again the 1 key. The most prominent 10-key machines on the market are the Dalton, the Moon-

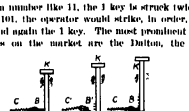

FIG. 5

FIG. 6

Hopkins, and the typewriter-adding machines like the Wahl, the Elliott-Fisher, and the Underwood.

Keyboard adding machines can, however, be divided according to their construction into key-driven and key-set machines.

Key-driven Machines.—The simplest key-driven mechanism is one something like the old Comptometer. (You will pardon me if I do not describe the actual construction of any machine, for in that way I cannot so easily be caught in an error. Besides, in the actual machine, the mechanism occurs in several layers, which cannot be so readily understood as a diagram laying it out in one plane.)

Reference to Fig. 4 will show that there are as many banks of keys as there are decimal places. In each bank there are nine keys, to which are given the values 1, 2, 3, 4, 5, 6, 7, 8, and 9. Each key is normally kept up by a spring. Underneath them a lever *GL* is extended, with a gear attached thereto. Normally it is held up by a spring. There is another lever *PL*, which co-operates with a pawl, that can be inserted in a gear *T*, which is in chain with the gear upon the gear lever. When a key is pushed down, there occurs initially some lost motion; that is, the key does not strike anything. A little later a projection *a* on the key strikes the gear lever *GL* and moves it. Just when the gear lever has moved an amount corresponding to the value of the key pushed down, the bottom of the key strikes the pawl lever *PL* and pushes the pawl into the teeth of the gear *T*, thus preventing overthrow. The gear lever thus has been pushed down by a key a number of steps equal to the value of the key. Namely, the 1 key has pushed the gear lever down one gear step, the 2 key two gear steps, etc., before locking occurs. There is a ratchet mechanism (not shown) between the gear lever and the totalizer wheel *T*, so that on the way up the gear lever does not rotate the wheel of the totalizer.

The above is practically the mechanism of the Ludlum machine and of the old Comptometer. In the new Comptometer some modifications have been introduced. For instance, the gear lever does not rotate the totalizer wheel on the down push of the lever, but on the return thereof. Again, there are two pawl levers, instead of one, permitting the making of a portion of the mechanism twice as large and therefore stronger.

In the old Comptometer, the carrying mechanism upon the wheels *T* was something as follows: (Fig. 4.)

Each totalizer wheel *T* was supplied with a cam *B*, which gradually extended further and further from the center, and which was provided with a sharp drop at one point. The drop was located at the point corresponding to 9. The cam co-operated with a tooth *C* on a lever *D*. The lever had at its outer end a pawl *E*, which could drive a ratchet wheel on the next higher wheel *T*. As the lower wheel *T* rotated, its cam gradually pushed back the lever *D*, storing energy in the spring *G*. When the drop of the cam *B* passed under the tooth of the lever, the latter was no longer resisted, whereupon it flew in, and by means of its pawl *E* pushed the next higher wheel forward one step. This carrying mechanism is irreversible; that is, it will not work if the wheel *T* rotates in the opposite direction; it accumulates successively and carries successively. It was used in the Comptometer, the Dougherty, the Fisher, and the Howleson machines. In the present Comptometer a modification of this older carrying mechanism is used, which still employs the cam and sudden drop.

Full-stroke Mechanism.—Let me call your attention to the fact that in the above machine, if the operator incompletely depresses any key, he will turn the totalizer wheel an insufficient amount. He will thus register a mistake in the machine. Such is actually the case with a good many machines on the market; for instance, the Burroughs non-listing machines. To prevent such a mistake, various mechanisms called "full-stroke" have been provided. They operate about as follows: (Fig. 5.)

Let *K* be a key with teeth on its edge. Let *B* be a pawl which by means of a spring *C* always tends to return to its central position if displaced. Obviously, the key can now move down, but the moment its teeth engage the pawl the latter swings down, assuming a position as drawn at *C'*, and prevents the key from rising. However, when the ratchet has moved completely past *B*, then the latter snaps up and the key is then free to move up again. Full-stroke mechanism is in use on the handles of many adding machines, for instance the Burroughs. It is also in use on multiplying machines such as the Brunsviga. Something similar is used as a part of the full-stroke mechanism of the keys of the Wahl.

Single-key Mechanism.—There are other troubles that are encountered in the operating of the keys. Suppose the operator inadvertently strikes two keys at once. What happens? In some machines, in fact in most machines, the result is a mistake. In others, the Wahl, for instance, it is impossible for the operator to depress two keys at once. This is prevented by what is called a single-key mechanism, constructed somewhat as follows:

Let A^1 and A^2 (Fig. 6) be the cross-sections of two key levers of a typewriter. Hanging between the key levers are some pieces B^1, B^2, B^3, whose width is equal to the distance between the centers of the key levers. On the outside of all the pieces *B* are two stops C^1 and C^2. The pieces *B* occupy all the room between the stops except the thickness of one lever *A*. Thus if one lever, say A^1, be depressed, it shoves B^2 and B^3, etc., to the right and B^1 to the left, and then continues without any interference. Should the attempt be made to shove two levers down simultaneously, they jointly take up too much room, and, therefore, both get jammed. The single-key mechanism is extensively used, not only on adding machines, but in cash registers and voting machines. Some of you must have wondered how it is that in the Chicago voting machines it is possible to vote for, say, only 10 out of 150 candidates. It is by an extension of the above mechanism.

(To be concluded.)

The Fluorescence of Petroleum Distillates*

By Benjamin T. Brooks and Raymond F. Bacon

FLUORESCENCE is one of the most striking characteristics of petroleum distillates, but its cause is not known, at least some of our best authorities attribute it to causes which have nothing to do with the phenomenon The heavier distillates from Pennsylvania and certain other crude petroleums have a marked greenish fluorescence, and the trade has come to associate this property with Pennsylvania oils. For some uses it is common practice to "debloom" the oils by sun-bleaching or by the addition of certain "deblooming" substances. The subject therefore has some practical as well as theoretical interest.[1]

Engler considers that the fluorescence of mineral oils is due to their colloidal character. Crude oils and the heavier distillates are optically nonhomogeneous and show a marked Tyndall effect, but this property cannot be considered as indicating colloidal properties since many organic compounds having large molecular weights show the Tyndall effect when in true solution. Schneider and Just[2] claim to have observed ultramicroscopic particles in a "yellow mineral oil" and a sample of "paraffine oil" Holde,[3] studying the physical condition of lime soaps in grease, stated that colloidal particles are not discernible as such under the microscope. It is probable, however, from the researches of Holde that such greases, as well as oils containing asphaltic or resinous matter, are to be regarded as colloidal, not *true* solutions. Schulz[4] claimed that the effect of adding "deblooming" substances, such as nitrobenzol and nitronaphthol, was merely that of adding something having a high refractive index, thus making the oil optically homogeneous.

This theory of fluorescence of mineral oils seemed very plausible. However, since many examples of nonfluorescent oleo-resinous solutions and mixtures are known, and since the fluorescence of mineral oils persists after repeated distillation and is quite marked in distillates boiling as low as 200 deg. Cent., we believed that resinous or asphaltic matter could not be a contributing factor Our experiments have shown that, in general, oxidizing agents partially or wholly destroyed the fluorescence. Certain facts suggested to us that sulphur or carbon in colloidal suspension might be the cause of the phenomenon. Stable colloidal suspensions of carbon in water and various organic liquids have been prepared[5] and described as nonfluorescent and brown to black in color. Sulphur, on the other hand, often shows bluish colors when in colloidal degree of dispersion, and the blue color of ultramarine blue is undoubtedly caused by so-called colloidal sulphur[6]

We have succeeded in proving that colloidal suspensions have nothing to do with the fluorescence of mineral oils.

Working on the theory that ultramicroscopic particles were present, 100 cubic centimeters of a highly fluorescent lubricating oil were diluted with kerosene to about 500 cubic centimeters in order to decrease the viscosity. The solution was placed in a suitable cell containing two round copper plates spaced 2 centimeters apart. The oil between the plates was subjected to a unit direction field of 30,000 volts potential difference for 30 minutes without any visible change in the fluorescence or flocking out of any kind of substance.

A sample of the same solution, carefully dried by calcium chloride, was filtered through the finest filter paper and examined under an ultramicroscope of the Zsigmondy-Siedentopf type, but no particles whatever were visible. It was found that unless the oil was carefully dried and filtered particles were visible in the light cone. These may have been minute drops of water or dust. The fact that the ultraviolet light cone is made visible to the eye with bright fluorescence has no significance so far as the colloidal theory is concerned, since as a general rule the wave length of the emitted fluorescent light is always greater than the incident ray, in this case from ultraviolet to visible blue. Furthermore, the ultraviolet cone contains a certain amount of the visible rays. No more rigid proof of the nonexistence of substances in colloidal suspension in carefully purified fluorescence mineral oil could be desired. In order, further, to test the arrangement and efficiency of our instrument, a colloidal gold "solution" was made by the formaldehyde reduction method, one of platinum by the Bredig method, and one of palladium by reducing with hydrogen according to Paal, and the beautiful results characteristic of this instrument were obtained.

Percolation through Fuller's earth is an excellent and well-known method for clarifying and bleaching oils. A sample of a highly fluorescent lubricating oil was allowed to run through a 5-foot tube packed with fine Fuller's earth. The resulting oil was very light in color but highly fluorescent, and when a little tarry matter, which gave brown nonfluorescent solutions in kerosene, was added to the oil until the color matched the original oil, the two could not be distinguished. The fluorescent material is therefore only slightly absorbed by Fuller's earth, and is probably not of very great molecular complexity.

While working on the colloidal suspension theory, the marked solubility of sulphur in mineral oils was noted. A 200 cubic centimeter sample of a light machine oil was heated to 100 deg. Cent. with an excess of flowers of sulphur, filtered hot, and on cooling about 0.5 gramme of sulphur crystallized out Guiselin[7] states that benzine dissolves 0.5 per cent sulphur at 20 deg. Cent. It is extremely improbable that a *stable* colloidal suspension could exist in which the solubility of one phase in the other is as great as in the case of sulphur and petroleum oils.

Carbon disulphide added to a fluorescent lubricating oil weakens the fluorescence almost to the point of extinction; what remains is dark greenish. Before making the experiments with the ultramicroscope, this was thought to favor the sulphur suspension theory, or the theory of Schulz based on optical homogeneity[8]

Further experiments with other solvents showed that the character of the fluorescence was affected by the various common solvents in the same way as in the case of the diamino derivatives of terephthalic acid methyl esters, studied by Kauffmann.[9] The effect of the various solvents was even more marked with solutions of the purified fluorescent material described below. The fluorescence colors observed were as follows:

Amyl alcohol .	Brilliant sky-blue
Aniline . . .	Very faint green, no blue
Benzol. . . .	Pure clear blue
Carbon disulfide	Faint green, no blue
Chloroform	Bluish green, passing into green on concentrating
Ether	Clear blue
Ligroin . . .	Blue
Phenol . .	Greenish blue
Pyridine . . .	Bluish green

In most cases the addition of *small* amounts of solvents having high refractive indices has practically no effect on the fluorescence. The effect of adding nitro compounds therefore must have an explanation different from that offered by Schulz.

The introduction of a nitro group into the molecule of a fluorescent benzol derivative, such as the terephthalic esters, completely destroys its fluorescence. It appears that a nitro group in the solvent has the same effect as a nitro group in the molecule of the active compound itself. This is not surprising in view of the marked effect of other solvents. We believe that possibly the fluorescent substance in mineral oil owed this property chiefly to the presence of one or more amino groups as auxochromes but, as will be shown below, this cannot be the case. Although we have found that oxidizing agents destroy the fluorescence, it is probable that the action of nitro compounds is purely physical since we have added N^2O^4, nitrated kerosene or nitrobenzol to fluorescent lubricating oils chilled to –10 deg. Cent. and destroyed the fluorescence. It is highly improbable that oxidation of any hydrocarbons could take place under these conditions since at 0 deg. Cent., N^2O^4 merely adds on to ethylene bonds without oxidation.[10] There is also the possibility that such compounds as picric acid and nitrobenzol form nonfluorescent addition products, or double compounds, such as is the case with pyrene and chrysene. However, the simple nitro paraffines are not known to form such double compounds, and "nitro kerosene" is fully as efficacious as nitrobenzol for neutralizing fluorescence. The following experiment is interesting in this connection: A sample of a highly fluorescent lubricating oil was "debloomed" by the addition of nitrobenzol. This oil was then shaken out six times with one-half its volume of 96 per cent alcohol, after which treatment the blue fluorescence had reappeared and exactly matched a sample of the same oil not treated with nitrobenzol, but shaken out with alcohol in the same way as the first sample. Refining such a "debloomed" oil with sulphuric acid yields a fluorescent oil identical in this respect with that obtained by refining the original oil. The action of nitro compounds in neutralizing fluorescence must, therefore, be purely physical in character.

The fact that exposure to the atmosphere for some time partially destroys and changes the character of the fluorescence suggested that what took place during this process was slow autoxidation.

Nitrous acid readily neutralized the fluorescence of lubricating oils, but the oils gradually became dark colored and resinous. Distillation of the latter dark colored oil *in vacuo*, or with superheated steam, yielded oil having a bluish fluorescence. Repeated washing with alkali removes only a small part of the coloring matter. Shaking a part of a sample of pale engine oil with nitrous acid for 3 minutes, followed by washing with water and filtering through Fuller's earth, gave a less resinous, light colored oil, very similar to that obtained by sun-bleaching. Oxides of nitrogen, generated by the action of dilute nitric acid on a metal, were then tried, and it was found that the sun-bleached oil could be matched with respect to color and fluorescence, provided the temperature of the oil was not permitted to rise above 10 deg. Cent. before washing with dilute alkali. At low temperatures addition of oxides of nitrogen to unsaturated compounds probably results as shown by Jegorow. Unless the oil is chilled before passing in the oxides of nitrogen oxidation appears to result, accompanied by rise in temperature, darkening in color and formation of resinous material. No method of removing the resinous coloring matter without at least partially restoring the bluish fluorescence was found. The effect on the color of the oil of nitric acid in sulphuric acid, when used for refining, is well known and constitutes one of the advantages of acid made by the contact process over that made by the chamber method.

We then made a series of experiments to determine the chemical properties of the fluorescent substance. The efficiency of sulphuric acid, particularly fuming acid, in removing fluorescence is well known It was found that the wash water from freshly prepared acid sludge tar, made by refining lubricating stock, was highly fluorescent. This suggested that the fluorescent material formed water-soluble sulphonic acids, or that the fluorescent substance was a base and removed as a soluble sulphate. The latter hypothesis can hardly be true since dilute acids do not exact the fluorescent material from the oil. A quantity of such fluorescent aqueous solution was made alkaline and extracted with ether, but no fluorescent material was obtained, indicating that the substance in question is not a base. A dilute acid solution of the fluorescent substance was nearly neutralized with lime to remove the excess of sulphuric acid. The filtered aqueous solution was evaporated nearly to dryness and the crystalline residue, containing sulphate of lime, extracted with alcohol Twelve liters of lubricating distillate yielded in this way about 1 gramme of an impure crystalline residue which was intensely fluorescent when dissolved in the different solvents named above. The amount obtained was too small to be thoroughly investigated, but we hope that we shall have an opportunity in the near future to prepare a quantity of this highly interesting material sufficient for further work. The above results were enough to show the general character of the substance. The crude fluorescent substance probably contains one or more compounds of the benzine series resembling, or perhaps identical with, chrysene, fluorene or pyrene. Such compounds are known to be formed by the pyrogenic decomposition of many organic substances. Klaudy and Fink, in 1900, isolated a yellow crystalline substance, giving highly fluorescent solutions, from the residuum of a cracking still. They gave it the formula $C^{20}H^{16}$.

A large proportion of the fluorescent substance or substances is formed during the distillation of the crude. This was shown by distilling a sample of Oklahoma crude at atmospheric pressure and under a pressure of 5 millimeter of mercury. The distillates in the first series were very much more fluorescent than the latter. This is also true of the distillates from coal when distilled at atmospheric pressure and under a pressure of 5 millimeters. Parallel with this difference it should be noted that substances of the benzol series form a much greater proportion of the coal tar obtained at ordinary pressures, paraffines and olefines constituting over 80 per cent of the coal tar obtained by distilling *in vacuo*. It is also well known that no fluorescent substances are known belonging to the paraffine series

Halogenation destroys the fluorescence, as is to be expected. Hydrogenation also destroys it.

Cement from Beets

IT is now reported that a French firm is making an excellent cement from a by-product in the process of making beet sugar. The scum that forms when the beets are boiled, and which has heretofore been thrown away, consists largely of carbonate of lime and water, and from 70,000 tons of beets treated 4,000 tons of carbonate lime is obtained; to this 1,100 tons of clay is added, the resulting product being 3,162 tons of excellent cement. The scum is pumped into large tanks, where it is allowed to dry partially; finely divided clay is then mixed with it; the mixture is thoroughly amalgamated by beaters for an hour and burned in a rotary kiln, much in the same way as Portland cement. The clinker is then removed and pulverized into cement.

"Suction" Between Passing Ships—III*

Important But Little Understood Forces Affecting the Motion of Vessels

By Sidney A Reeve, M E

Concluded from SCIENTIFIC AMERICAN SUPPLEMENT No 2037, Page 48, January 16, 1915

IV ACTUAL INSTANCES OF "SUCTION" COLLISION

The following descriptions are condensed from the records of the American Admiralty courts Usually the quotations are from the decision handed down by the court summing up and balancing the conflicting testimony Wherever possible charts of the date of the collision have been consulted

Case 6 Andus Saratoga September 21 1877 Hudson River near Albany (Fig 12) A southbound tow consisting of eleven barges banked three abreast was moving parallel with the dike (really a wharf the true dike being on the opposite side of the river) The steamer Saratoga 300 feet by 66 feet also south bound undertook to pass between the tow and the wharf When the bow of the S had overlapped the aftermost barge some 40 feet the tow sagged down with the wind (which was westerly but very light) against the S The court held that the wind theory was not upheld by the facts and hence disbelieved that the sagging occurred at all The term suction was not mentioned but in the light of later knowledge it is a clear case The courses are such that a shoaling of the water from 14 feet to 9 feet occurs just where the wharf also converges on the courses The vessels probably had a draught of about 6 feet and their aggregate beam amounted to nearly the width of the channel Under such conditions suction was inevitable. But its hydraulic theory in this case falls more under that of canal-waves than of two-dimension stream-lines which former the student will find discussed in the references listed in the first article of this series page 31 ante

Case 14 Aurania Republic September 19 1885 3 24 P M 2 miles northeast by east of Sandy Hook (Fig 13) This is the first recorded suction collision between first-class liners In fine weather with sea smooth tide flood and wind light the A (480 feet by 56 feet by 20 5 feet draught 14 7 knots) and the R (420 feet by 42 feet by 25 2 feet draught 13 2 to 13 5 knots) collided as they were about to enter Gedney Channel the stem of the R striking the port quarter of the A when the latter's stem was about 100 feet west of the buoy (double circle in Fig 13) The A had come down the (old) Main Ship Channel and the R down Swash Channel Each vessel headed for the buoy There is the usual conflict of testimony as to locations and courses but the agreement is closer than usual The court concluded that the ships were on courses converging by 1½ points as drawn but this conclusion disregarded the R's claim as to angles and distances because at a distance of 500 feet to 700 feet apart one minute before the collision no possible suction port helm or other influences from the A could have had any sensible effect upon the R at that distance or have sensibly neutralized or delayed the effect of the hard a-starboard helm which her officers say the R was then under and in spite of which as they say the vessels came together But had the court been equipped with an adequate theory of suction the decision would probably have been reversed The court was misled by the idea that suction is a force drawing the two hulls bodily together whereas it is almost wholly a sheering or swinging pair of forces one attracting the bow and the other repelling the stern It is the forward momentum of the pivoted vessel and not the attraction of suction which brings her into the other ship Thus in this case the R was traveling at about 1 350 feet per minute According to the court's theory the point of collision was only some 170 feet to starboard of the R's course At her rate the suction-sheer need have been through an angle of only two points beginning one-quarter minute before the impact to have cleared the space between the two vessels and at its inception the ships would have been only 400 feet or 500 feet apart

Most of the witnesses on both sides seem to agree that shortly before the collision the stem of the R seemed to be approaching the A's quarter more suddenly and rapidly than their previous angle of convergence would account for The evidence leaves no doubt that the R's engines were stopped and reversed just prior to the collision The court knowing that the R carried a hard a-starboard helm and finding no other explanation, attributes the sheer to the 4-mile breeze! Navigation would be hazardous indeed if a 4-mile breeze could entail such a disaster

Fig 13 (from a chart of 1884) shows that the water was shoaling rapidly beneath the A at the rate of 15 feet in a ship's length at the time and place of collision This coupled with the convergence of courses at an angle variously stated as from 10 degrees to 38 degrees was undoubtedly the cause of the overwhelming suction Although an unknown depth of tide must be added to the soundings of the diagram the ships were drawing most of the water to be had beneath the A's stem Had they met a minute later over a flat sea-bottom, they would probably have escaped disaster This same locality became the scene of another suction collision (case 35) between sea-going liners but at a later date when dredging had deepened the shoal spots

Case 17 Hartt - 'City of Brockton, September 29, 1887 outside Sandy Hook The B (paddle-steamer 283 feet long) overtook the tug H (125 feet long) as both were going to an international yacht race When Sandy Hook was passed and South Channel reached (see Fig 13) at about the time when the paddle-box of the B was abreast of the pilot-house of the H the latter gave a sudden lurch towards the B which shortened the distance between the two about one-third The H then straightened up Then she lurched again toward the B and instantly the collision occurred the bow of the H striking first the port paddle-box of the B and then running under the B's port guard where

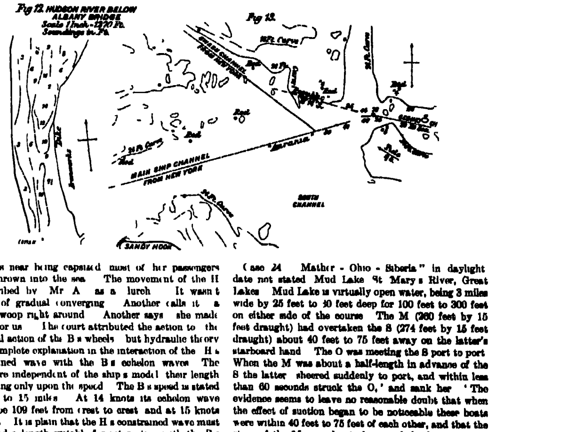

Fig 12 HUDSON RIVER BELOW ALBANY BRIDGE Scale 1 Inch=1370 Ft. Soundings in Ft.

she was near being capsized most of her passengers being thrown into the sea The movement of the H is described by Mr A as a lurch It wasn't a case of gradual converging Another calls it a grand swoop right around Another says she made a dive for us The court attributed the action to the powerful action of the B's wheels but hydraulic theory finds complete explanation in the interaction of the H's constrained wave with the B's echelon waves The latter are independent of the ship's model their length depending only upon the speed The B's speed is stated as 14 to 15 miles At 14 knots its echelon wave would be 109 feet from crest to crest and at 15 knots 125 feet It is plain that the H's constrained wave must have had a length suitable for interaction with the B's echelon As one echelon crest came into phase the H took its first lurch As the next crest came into phase the second lurch occurred It is not likely that the sea-bottom was a contributing cause though there are banks about 20 feet deep in this vicinity which may have helped

Case 18 'Switzerland - La Gascogne,' January 21, 1888, New York Upper Bay, both vessels bound to sea water 60 feet to 75 feet deep In clear daylight with no other vessels interfering, the L G (480 feet by 52 3 feet 7,415 tons gross 15 to 16 knots) having come up with the S (329 feet by 38 8 feet, 2,601 tons, 9 to 10 knots), was passing her on the port side at a distance estimated by various witnesses at 150 feet to 300 feet The bow of L G had drawn ahead of the bow of the S when the vessels came into collison, the S's bow striking L G on her starboard quarter at an angle of about 30 degrees The lower court held the S at fault, but the upper court reversed this Both courts, in order to develop a consistent explanation in lack of true hydraulic theory, were forced to disregard some well-founded evidence But with suction properly in mind no violence to the facts is needed The L G had to port somewhat at this point in the channel, and a very slight convergence of the two courses, if not noticed immediately by the S, would bring the latter into control of suction very quickly Collision might occur from this cause within 43 seconds from an original distance of 250 feet or in 26 seconds from 150 feet, if the L G's porting had been only one point

Case 20 'Devereaux'-"Folsom'-"Mitchell," August 13, 1890 This was the first case in which the court considered suction as a cause when the vessels were passing in opposite directions It occurred in a dredged channel between Lakes Huron and Michigan, about 300 feet wide by 25 feet deep The D (270 feet by 37 feet) passed at 4 knots the tug F (185 feet by 35 feet), and sheered enough, uncontrollably, as she did so to collide with the schooner M in tow of the F The tendency of every ship to 'smell a bank and sheer away from it was mentioned in the decision, and it is certain that this tendency would be exaggerated at the moment the F passed

Case 21 'City of Macon'-'Nedjed," December, 1890 Savannah River a variation of the preceding case When the M (about 300 feet long) was partly lapping the N (320 feet by 45 feet by 19½ feet draught) about 100 feet away in a channel 400 feet to 450 feet wide by 20½ feet deep, the N sheered across the M's bows, away from the wharves, and ran in the mud-bank opposite

Case 24 Mather - Ohio - Siberia" in daylight date not stated Mud Lake St Mary's River, Great Lakes Mud Lake is virtually open water, being 3 miles wide by 25 feet to 30 feet deep for 100 feet to 300 feet on either side of the course The M (260 feet by 15 feet draught) had overtaken the S (274 feet by 15 feet draught) about 40 feet to 75 feet away on the latter's starboard hand The O was meeting the S port to port When the M was about a half-length in advance of the S the latter sheered suddenly to port, and within less than 60 seconds struck the O,' and sank her 'The evidence seems to leave no reasonable doubt that when the effect of suction began to be noticeable these boats were within 40 feet to 75 feet of each other, and that the stern of the M was about abreast of the foregigging of the S At this point it is in evidence from both sides that the speed of the S seemed to be increased, and that she ran up on the M some 10 feet or 15 feet Yet it is uncontradicted that the steam of the S was not increased This temporary increase of speed by the slower boat is shown to be one of the effects of suction It has been argued that, if suction had exerted any force upon the navigation of the S, it would have shown its effect by attracting or drawing her closer to the vessel within whose influence she was, and not as a repulsing force throwing her off to port But evidence of just such an attractive force appears" Evidence is then quoted by the court tending to show that the S was first drawn in towards the M, and then, later, whether assisted by a starboard helm or not is not known, sheered off toward the O The facts emphasize the instability of steerage under such conditions. Perhaps a hard-a-starboard helm was assumed when the first sign of suction appeared, and thus, after steadying her against the suction, carried her too far to port for her to recover within the 30 seconds available before she met the O. Or the lack of testimony as to the helm of the S might suggest a jammed helm. In any event suction was plainly the original cause of the disaster.

Case 25: "Aurania"-"Wilhelmina," January 12,

* Reproduced from Engineering

1898, 2 P. M.; Delaware River, about 1 mile down Deep-Water Point range, with apparently ample room laterally, but very little depth. The bottom is even, but the charted depths are everywhere less than the draught of either ship; tidal depth not known. The A (345 feet by 46 feet by 23 5-25 feet draught) overtook the W (325 feet by 41 feet by 22 5-24 5 feet draught) on the latter's port hand, passing at distances variously stated as from 75 feet to 300 feet, the court favoring the smaller distances, as from more reliable witnesses. 'Before the A's bow was opposite the W's bridge the W's pilot ordered the wheelsman to port the helm because he saw the A was coming too close. When the A's bows got abreast of the W's bridge, he says he told the captain to slow the ship to half-speed and that when her stern got somewhere about half way between the W's fore-rigging and the bridge he had the engine stopped; that he then asked if the wheel was a-port and that the chief officer replied that it was hard-a-port; that he then went and looked himself and found that it was so and that the A was at that time about 75 feet to 100 feet away." When the A's stern came forward of the W's bridge the W took a sheer and struck the A a glancing blow upon the starboard quarter about 35 feet from the stern. 'This sheer of the W the pilot accounts for by what he calls suction. Both vessels had to return to Philadelphia.

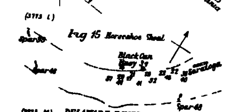
The court referred to the cases of the Folsom, the "Cleveland, the Unit, the Marnl and the Brock ton." The cases above referred to judicially recognizing the existence of the force called suction and its power under favoring circumstances to draw one vessel towards another, cannot be disregarded by this court.

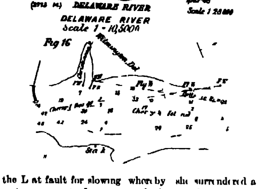
Case 26. Masaba - Smith - Aurania,' on a bright July day in 1898 in the dredged channel in Lake St Clair above Detroit. In 1898 the St Clair Channel was 350 feet to 400 feet wide by 20 feet deep; the Detroit channel 800 feet wide, and of equal depth. As it is not stated just where the collision occurred, both widths are given in Fig 14, which is drawn to scale as to the lengths of the ships and tow line, but not as to lateral distances, which are unknown. The case is cited as an interesting one of three-ship action, which is plainer from the diagram than from the description. The S was apparently not affected by the M until the Aurora was met, although the first two had been traveling at not widely differing speeds. The S recovered from her first sheer, apparently caused by her bow entering the Aurora's lateral depression, but took a second and uncontrollable sheer just after passing the Aurora. 'The 'Aurania's' helm was hard-ported and the Aurora's' engine stopped and the lever controlling the towing-machine on the Aurora released so that the cable might reel out; there being no time or opportunity to let go the line on either vessel; but so extreme and rapid was the sheer of the S that she struck the tow-line at nearly a right angle about 100 feet ahead of the 'Aurania,' parted the wire cable and then swung around the bow of the 'Aurania' which struck the S on the starboard quarter. The vessels came together with great force driving the bow of the A to port and straightening the S up in the channel, so damaged that she filled and sank after going a short distance, while the A with bows badly stoved forged ahead and drifted diagonally down and across the channel until she brought up on the bottom, aided in this by a stern anchor which she had let go.'

Case 35. 'Martello - Mesaba, September 22, 1900, 10.42 A. M., New York Lower Bay entrance to Gedney Channel, Fig 13, but by this date dredging had reduced the slope of the bank to about 10 feet in a ship's length. Nor is the place of collision so exactly located as in the case of the 'Aurania'-"Republic." An ebb-tide of 1 knot was with the ships. Both ships went down the old Main Ship Channel. They passed Sandy Hook with the "Martello" (370 feet by 43 feet by 28 feet draught 10 knots) said to be one-third mile ahead of the Mesaba' (482 feet by 52 feet by 29¼ feet draught 13 knots) but if this gap was closed by the time they reached Gedney there could have been a difference of only about 3 knots in their speeds. While the 'Mesaba' was passing the 'Martello" on the northern side, 'probably from 100 feet to 150 feet' distant, when the Martello's stem was about abeam of the Mesaba's amidships or a little more aft, the 'Martello's' bow was seen to turn to port toward the 'Mesaba,' and it continued to turn more rapidly as the 'Mesaba' advanced, until the bluff of her port bow, about 20 feet from her stem struck the starboard quarter of the 'Mesaba,' about 100 feet forward of her stern, a violent blow. The 'Martello' was obliged to return to New York, while the 'Mesaba' continued her voyage." The court held that suction was the cause of the collision.

Case 37: "North Star"-"Nourmahal," September 28, 1901, 4 P. M. Swash Channel, New York Lower Bay (Fig. 13, just beyond the northern edge of which, where the eastern bank of Swash Channel is steeper, the collision occurred). The yacht N (247 feet by 30 feet by 10 feet to 16 feet draught, 15 knots) was overtaken on her starboard hand by the N S (320 feet by 46 feet by 13 feet to 15 feet draught 17 knots). When the yacht was about 600 feet ahead of the N S they were apparently something more than 100 feet apart but were drawing slightly nearer and when the N S's stern reached a point about opposite the bridge of the yacht the latter being influenced by the N S's suction turned towards her and the vessels came together notwithstanding a starboard then hard a-port helm on the part of the yacht. There was no change in the course of the N S. The collision can be accounted for in no other way than as a result of suction. The N S was held solely at fault.

Case 39. Denver - Lehigh. March 31, 1900, 5.15 P. M. New York Lower Bay below West Bank Light. The steamer D (390 feet by 17½ feet to 23 feet draught 12 to 12½ knots) overtook and partly passed the sea-going tug L (150 feet by 15 feet draught) (almost as fast). The L was following a slightly converging course on the D's port hand about 150 feet distant. When the stem of the L was abreast or slightly forward of the port side of the D's bridge the L which was bound up Raritan Bay to D's starboard slowed her engines to let the D get well ahead and was instantly caught in the suction of that vessel and drawn against her side, contact occurring with the bow of the L against the D's port quarter some 40 feet from the stern with the tug at right angles with the steamship. Court held





the L at fault for slowing whereby she surrendered a certain amount of power and became less manageable. Damages were divided. The water was 28 feet to 31 feet deep with no marked lumps in the bottom.

Case 41. Saratoga - Taunton. June 17, 1907. Delaware River Horseshoe Bend (Fig 15). This is an interesting case of bank-sheer. The S (430 feet by 50 feet by 18 feet draught) coming down the river at 8 knots with a helping tide of 2 to 2½ knots struck and slipped off the seventeen foot lump at buoy 37, sheered suddenly about 4 points across the channel and collided with the T.

Case 43. Parima - Prinzessin Irene. April 4, 1908. New York Lower Bay. 700 feet to 1,000 feet north of the buoy on point of the shoal between Main Ship and Swash Channels and 1,700 feet to 1,800 feet west of the red bell-buoy. No court decision was ever rendered on the facts of this case the following outline being the result of the author's attendance at the trial. The P (335 feet by 42 feet by 21.3 feet to 23 feet draught) was going down Main Ship Channel at 10¼ knots when she was overtaken on her starboard hand by the P I (524 feet by 60 feet by 22.6 feet to 24.8 feet draught) at an estimated speed of 13.8 knots. The ebb tide increased those speeds about one knot and altered their apparent course 4 degrees or 5 degrees eastward. When the bow of the P I was abreast of the P's mid-length and from 150 feet to 250 feet distant the P sheered to port, ran over the perch-and-square buoy, and ran aground. The P libeled the P I as being the overtaking vessel and the cause of her going aground.

The case is, in the writer's belief, a plain case of repulsion of the leading ship during the first phase of passing. The water, which shows a general depth of 31 feet to 32 feet (plus 2 feet of tide), is amply restricted to account for the sheer, which took place against a hard-a-port helm. In addition, the 1:40,000 chart of New York Harbor shows a single sounding of 22 feet at or just north of the place of sheer, but a chart of 1:5000 which appeared in court did not fully corroborate this lump. But even without it a sheer on the part of the smaller ship passed at such speed and propinquity by a vessel of over three times her tonnage drawing most of the water in the channel would be only natural. This case is of further interest in that the officers of the P I were not aware until they reached Germany that their ship had been regarded as connected with the accident in any way.

Case 44. Monterey - United States. April 16, 1908, 1.30 P. M. New York Lower Bay. Main Ship Channel just above the entrance to Swash Channel in almost the identical spot of Case 43 except further toward the westward side of the channel. Weather clear, wind light, tide last of ebb netting 0.8 feet below the mean low water of the chart soundings. The twin screw steamship M (341 feet by 47½ feet by 20 feet draught 12 knots) was overtaken about abreast of the bell buoy and well over to the westerly edge of the channel by the U S (501 feet by 58 feet by 27½ feet draught 15 knots) which was converging on the M's course by a half point. The clearance was stated as anything from 75 feet to 800 feet (the entire width of the channel being 1,100 feet) the court favoring 100 feet. As the U S drew up abreast the helm of the M was kept steady a port, a caution to the wheelsman to keep her perfectly straight and counteract any tendency of the vessels to veer together. When the U S was from one-third to one-half past and the bow of the M was opposite a point about two points abaft the beam of the U S the M turned in the direction of the U S notwithstanding a hard a-port helm and the starboard engine being put full-steam astern and the port engine being kept going ahead to assist the port-helm. Upon its being found that these precautions did not have the desired effect both engines were reversed at full speed but the collision occurred, the bow of the M striking the starboard side of the U S at an angle of about two points. There were two blows on successive ding the other almost immediately. The U S was damaged to such an extent that it was necessary to beach her. The M was also seriously damaged but she remained afloat.

The lump in the bottom of this channel mentioned in connection with Case 43 apparently extends entirely across the channel. The depth at the black spar buoy opposite the red bell buoy was 26.2 feet that day. Considering that the M which must have been close to this buoy was drawing 20 feet while the U S drew over 27 feet the slightest lump in the bottom would suffice in addition to the half point of convergence to develop a suction sheer. The lateral proximity of the bank on the M's starboard hand would also contribute a strong tendency to sheer to port towards the U S.

It is also to be noted that whereas in many cases of suction the sheer occurs in spite of hard-over helm, in this case it defied the controlling power of twin screws as well. In the Chicago - Oswego case (not reported here) the latter vessel when she sheered dragged one tug sideways through the water broadside and overcame the direct engine power of another working in conjunction with partial power from her own engines. Such facts as these show how uncontrollable is the force of suction when once initiated.

Case 45. Murcia - Saf... November 26, 1908, 2 P. M. Delaware River, Cherry Island, about opposite Wilmington, Del. (Fig 16), weather clear and calm, flood tide. In the cut, which is about 700 feet wide by 33 feet deep by chart or 29 feet by testimony, the M (303 feet by 41 ... by 21 feet draught) was overtaken on her port side by the S (325 feet by 47 feet by 21 feet draught). Speeds are not stated; clearance stated contradictorily but according to the S 300 feet to 400 feet. According to testimony on behalf of the initial clearance when they began to overlap was 100 feet to 150 feet, but that as the S gradually drew ahead of the M the former converged slightly upon the course of the M so that when the S was about half way by the M the distance between them had been reduced to from 50 feet to 100 feet when the engines were slowed, then stopped and finally put full speed astern and the helm a-port. Notwithstanding this maneuver the M continued to approach the S more rapidly and then gave a sudden dive in the direction of the latter, the bluff of the M's port bow striking the S on the starboard side at a point about 100 feet forward of the latter's stern. Both vessels were injured.

The court quoted the opinion of Judge Gray in Case 25. In this present case however in contrast with Case 39 the pilot of the overtaken vessel was commended for slowing his engines. In this case too as in several others the court leant toward the smaller of the variously stated clearances on the ground that the time available would not permit the sheering vessel to cross a wider intervening space. But as nearly all these decisions have been rendered without any more accurate idea of suction than as a bodily attraction between the

two hulls the rapidity with which a ship in motion can cross lateral space by being rotated rapidly while she moves ahead—which is what suction does as well as accelerate the forward motion at the same time—has not been appreciated by the court. This line of reasoning annuls the court's conclusions as to the probable actual clearance and makes it probable that many of these suction sheers occurred under initial clearances much greater than those stated in the court decisions.

Case 47. Kennebec—Strathnairn, January 26, 1910, 8 A. M. Patapsco River, Baltimore Harbor; weather clear, wind light, tide early ebb. The S. (380 feet by 52 feet by 24 feet draught, 2,811 tons, 5 or 6 knots) came down the Sparrows Point Channel (100 foot wide by 25 feet deep) and made the almost square turn of 70 degrees into the Brewerton Channel (600 feet wide by 30 feet deep). There she met on her starboard hand the K. (250 feet long, 1,930 tons, 7 to 9 knots) also going down Brewerton Channel. When the ships met their courses were parallel or slightly converging, the S. being from 250 feet to 300 feet ahead, so that the K. overlapped by 75 feet to 100 feet; lateral distance not stated. The vessels came together in the usual suction manner but without room for as much angular rotation as usual, nor were the speeds high. Consequently the K. struck the S. with the side of her bow and while each vessel was damaged neither was disabled.

NEW BOOKS, ETC.

Briefer Physiology and Hygiene. With Practical Exercises. By Buel P. Colton, A.M., and Louis Murbach, Ph.D. New York: D. C. Heath & Co., 1914. 12mo.; 388 pp.; illustrated.

In this revision of a well known text Prof. Murbach seeks to retain all the pedagogical values while embodying such newer views and data as are required in the first two years of a high school course. Correlated subjects have been unified and the text so arranged that it may be used for one-third year, one half year, or a whole year's work. There are many new illustrations and questions replace the old summaries.

How to Make a Low Pressure Transformer. By Prof. F. E. Austin, Head of the Department of Electrical Engineering at Norwich University. New Hampshire: 14 pp. Price, 25 cents.

This little manual gives plain directions for making a transformer which will change 110 volts to 8 volts as a minimum. It can also furnish a variety of pressures from 8 to 110 volts. It is rated as a 100 watt transformer. The directions are simple and plain, so that any one having a knowledge of electricity sufficient to operate the instrument should find no difficulty in following them in its construction. The transformer will light small tungsten lamps, run motors for fans or toy railways, ring bells, operate sparking devices for gasoline engines, and serve for many experiments.

Le Hasard. By Emile Borel. Paris: Librairie Félix Alcan. Price, 3 francs 50 centimes.

A thorough discussion of chance is possible only in a work of a mathematical character so profound that it would be hopelessly beyond the ordinary reader. But it is possible to give some idea of the methods which are employed by the mathematician in determining the probability of a certain thing's happening or not, and also to show how important it is to apply the doctrine of chances to science and to human affairs. Prof. Borel has performed this task extremely well. His book is divided primarily into three parts. The first is an exposition without superfluous formulæ of the principles of the doctrine of chance such cases as fall within the theory of limited and unlimited alternatives and of inverse probability being taken up. The second part is devoted to the applications of the laws of chance to various sciences, such as sociology, physics, astronomy, biology and chemistry. The third part is of a philosophical character and gives the reader an idea of the manner in which chance plays its part in human affairs.

Historic Homes of New England. By Mary H. Northend, Author of "Colonial Homes and Their Furnishings." With numerous illustrations. Boston: Little, Brown & Co., 1914.

For many years Miss Northend's name has been familiar to the readers of monthly magazines devoted to the home as a writer on New England life. A resident of Salem and a member of a family well known in New England she has brought to her work the sympathetic understanding which is to be expected of one whose character had been molded by the traditions of New England. In her present work she takes us by the hand as it were into the old mansions which have made New England architecturally famous—the House of the Seven Gables, the Pickering house, the Rogers house, the Adams house, the Governor Dummer mansion and others. Her descriptions of these wonderful old dwellings and her beautiful photographs of their exteriors and interiors should prove inspiring to our architects and to those who have a love for the best in our colonial architecture.

Dynamic Evolution. A Study of the Causes of Evolution and Degeneracy. By Casper L. Redfield. New York: G. P. Putnam's Sons, 1914. 12mo.; 210 pp. Price, $1.50 net.

Dynamic Evolution puts forward a theory of animal energy and postulates rules governing its transmission in increased or diminished quantity. A close examination of pedigrees in stock is used as the foundation of the argument, which proceeds logically toward its application to man and mentality. The conclusion drawn is that transmitted energy, whether physical or mental, increases up to an advanced point with the age of the father. In support of this theory the author advances the fact that in the case of ten of the world's greatest men the average age of the fathers at the time of the sons' births is found to be no less than 55 years. The ten notables are Aristotle, Augustus, Bacon, Buddha, Confucius, Cuvier, Franklin, Humboldt, Ptolemy II and Solomon. Sons of young fathers are declared to be inclined toward militarism and aggressiveness; sons of more mature sires to the fine arts and statesmanship, while the old fathers convey moral and philosophical bias.

Electric Cooking, Heating and Cleaning. A Manual of Electricity in the Service of the Home. By Maud Lancaster. Edited by E. W. Lancaster, A.M. Inst. C.E. American Edition revised by Stephen L. Coles, formerly Managing Editor *Electrical Review*. New York: D. VanNostrand Company, 1914. 8vo.; 329 pp.; 305 illustrations. Price, $1.50 net.

In England there are a score of districts where electricity for household purposes is obtainable at a cost of one cent per unit. As the American charges vary from 3 to 20 cents per unit, the advantage our English cousins possess—an advantage of which they have largely availed themselves—may be readily appreciated. Even under the handicap of high cost, however, the essential cleanliness and convenience of this service is daily widening its appeal. The attractive volume in hand, written by a woman especially for women, shows all the modern devices for cooking, heating and cleaning electrically and describes their practical operation. The enthusiasm of the author is contagious, her points well made and not to be overlooked is her strict attention to economy. The work is carefully adapted to the requirements of the American reader and no small proportion of the apparatus it illustrates is of our own manufacture.

The Gas Turbine. By Norman Davey. New York: D. VanNostrand Company, 1914. 8vo.; 248 pp.; illustrated. Price, $4.

Of the two existing works in English on the gas turbine, the early monograph by Suplee is now (and it may be said with Norman Davey) because it has nothing to say about the Holzwarth turbine, while Herr Holzwarth's book is inadequate because it has nothing to say of anything else. Mr. Davey gives us a comprehensive view both of theory and practice, and his contribution is opportune and welcome. Of the three types of gas turbine, the constant pressure mixed fluid has been hitherto slighted. Considerable attention is here given to that type. A study of the variation in thermodynamic constants and its effect upon efficiency concludes the theoretical division of the volume. The discussion of practice includes the accessory machinery and practical limitations, summarizes efficiencies and compares types, and regards the gas turbine in the light of history, of experimental progress and of future possibilities. A list of turbine patents from 1856 to 1913 is appended.

The Mississippian Brachiopoda of the Mississippi Valley Basin. By Stuart Weller. Illinois State Geological Survey, University of Illinois, Urbana, 1914. 4to.; text, 508 pp.; 83 plates separately bound.

The fossil yield of the Mississippian formations is exceedingly rich and the present monograph is only a beginning toward a compact and accessible literature of their forms. All the known brachiopods of the region are described in this report, known as Monograph I. It discusses each species and records the geological formation of which the species is a member. The volume of plates invariably mentions the exact locality of the specimen illustrated.

Steel Construction. A Text and Reference Book Covering the Design of Steel Framework for Buildings. By Henry Jackson Burt, C.E. Chicago: American Technical Society, 1914. 12mo.; 381 pp.; illustrated.

In a handy, attractively bound little volume a well known and thoroughly competent structural engineer sets forth facts and formulas governing the erection of steel framework for buildings. Basic principles are lucidly explained. The practical illustrations accompanying the formulas conduce to independent thought on the part of the student, and at the same time demonstrate current practice. A sixteen-story fireproof hotel is presented in a complete set of drawings with all necessary explanations and details.

Card Reading. By Minetta. With Introduction by Sepharial. Philadelphia: David McKay. 12mo.; 104 pp.; illustrated. Price, 50 cents.

The more impressionable sex may derive a dubious sort of pleasure from the dictum of the cards upon such vital questions as "Who is near to me? Who is dear to me?"—though one would think the answers to these scarcely required a resort to occult aid. The introduction seeks to place cartomancy upon a scientific basis. The result can by no stretch of courtesy be called convincing to the average intelligence.

Alchemy, Ancient and Modern. By H. Stanley Redgrove, B.Sc. (Lond.), F.C.S. Philadelphia: David McKay. 8vo.; 141 pp.; 16 full page illustrations. Price, $1.50 net.

The old alchemy, whether regarded as a philosophy or a chemistry, is not devoid of interest. In its better-known, chemical aspect it inspired research, formulated laws and evolved into practical pursuits. Admitting this, "Alchemy, Ancient and Modern," by devoting nearly a hundred of its one hundred and forty-one pages to the charlatans and charlatanry of a dead day, must be regarded rather as an historical study of curious human traits than a monograph on radio-activity, which is lightly disposed of in one short chapter. For this reason the work will commend itself to him who dreams in the past rather than to him who lives in the present.

Psycho-Therapy. Its Doctrine and Practice. By Elizabeth Severn, Ph.D. Philadelphia: David McKay. 8vo.; 211 pp. Price, $1.25 net.

It is seldom that we have a book of this nature from a pen of such broad culture and practical philosophy. If the author claims too much for her method toward her personal attainments she exhibits an admirable modesty and restraint. Her knowledge of human nature is so true that involuntary chuckles escape the reader from time to time. She represents the best side of mental treatment, shorn of all the isms that so frequently turn it to disaster. She does not seek to establish psycho-therapy upon a religious basis. Several chapters of the work may be read solely for the instructive glimpses they afford us of our frailties and the inner strength that may be summoned to overcome them. A novelist would find these a mine of character in which the author's own character is the richest nugget. Withal her arguments are so circumstantially marshaled that we occasionally find ourselves convinced against our will.

Air, Water and Food. From a Sanitary Standpoint. By Alpheus G. Woodman and John F. Norton, of the Massachusetts Institute of Technology. New York: John Wiley & Sons, Inc., 1914. 8vo.; 248 pp.; illustrated. Price, $2 net.

The three previous editions of this textbook have been favorably received, and as the present edition embodies the various advances that have been made in analytical methods it should meet with a like kindly reception. Originally written from the missionary standpoint it has come into somewhat wide use as a text for colleges and technical schools. In it the three great essentials of our human existence are discussed in their relationship to health. Known facts are interpreted in an unprejudiced manner, and analytical methods take up much of the allotted space. Upon all the subjects dealt with a wider and surer knowledge is a crying necessity, and the work is deserving of a growing circle of readers that shall pass on its teachings to the lasting benefit of their communities.

Bill's School and Mine. A Collection of Essays on Education. By William Suddards Franklin. South Bethlehem, Pennsylvania: Franklin, MacNutt & Charles, 1913. 12mo.; 98 pp. Price, 50 cents.

"Bill's School and Mine" is in the large a contrast between the free boy life of the open country and the restricted environment of encroaching civilization. Other papers follow on "The Study of Science" and "Part of an Education," all exhibiting a breadth of culture and a keen outlook on the part of the writer that is as rare as it is energizing. He not only has a distinctive way of saying things, but he has distinctive things to say. His remarks on the study of physical science are so embracing as to the various phases and difficulties of the question that we can but wish all parents, teachers and students might read and profit by them.

The Art Commission of the City of New York. Report for the year 1913. 8vo.; 32 pp.; illustrated.

Aside from a list of the members and of committees appointments this Report mainly concerns itself with the various public structures and works of art passed upon by the Committee during the year. It is enlivened by both approved and disapproved designs, as in the cases of the Ericsson and Bowne memorials and the first subway plans. There are photos of old New York buildings of historic and architectural interest. A general sketch of the year's activities forms the subject-matter of the main section. The scope of the Commission is detailed, and there are illuminating paragraphs upon what constitutes true art in certain special instances and mistakes. The Report should be of interest to all who have the embellishment of the city at heart.

The Spectroscopy of the Extreme Ultra-violet. By Theodore Lyman, Ph.D. New York: Longmans, Green & Co., 1914. 8vo.; 135 pp.; with diagrams. Price, $1.50 net.

Since the absorption of air is slightly apparent in the ordinary ultra-violet, the smaller portion of this monograph deals with that region of the spectrum which lies between wave-lengths 4,000 and 2,000. This is introductory to the real discussion, which is a study of the Schumann or extreme ultra-violet region. In this investigation Prof. Lyman deals with apparatus and methods, with the absorption of solids and gases and their emission spectra, and with photo-electric and photo-chemical phenomena. The author need not have apologized for the restricted field of his monograph. The careful research here detailed opens up a wide horizon and physicists will welcome a handbook dealing exclusively with so interesting a subject.

SCIENTIFIC AMERICAN SUPPLEMENT

Founded 1876

NEW YORK, SATURDAY, JANUARY 23, 1915

Charles Allen Munn, President
Frederick Converse Beach, Secretary
Orson D. Munn, Treasurer

All at 361 Broadway, New York

Entered at the Post Office of New York, N. Y., as Second Class Matter

The Scientific American Publications

Scientific American Supplement (established 1876) per year	$5.00
Scientific American (est. 1845)	3.00
American Homes and Gardens	3.00

The combined subscription rates and rates to foreign countries including Canada will be furnished upon application.

Remit by postal or express money order, bank draft or check

Munn & Co., Inc., 361 Broadway, N. Y.

The purpose of the Supplement is to publish the more important announcements of distinguished technologists, to digest significant articles that appear in European publications, and altogether to reflect the most advanced thought in science and industry throughout the world.

Plancton, the Ultimate Food

Vast Resources of the Ocean from Which the Fish Obtain Their Sustenance

One of the most brilliant achievements of modern biology is the demonstration of the vast variety, bulk, and importance of the living creatures, both animal and vegetable, which swarm thickly in the clearest sea-water, and are known collectively by the name of plancton. Since the ocean covers two-thirds of the surface of the globe, and since these aquatic forms of life exist throughout many fathoms of depths, instead of merely in a thin layer of earth and air as do terrestrial creatures, it is obvious that they are enormously superior in numbers and in actual "tonnage."

But the very tiniest of these, the low vegetable forms which derive their nutriment directly from the water and its inorganic constitutents, themselves become the food for slightly higher forms of animal life, and these in turn feed still higher forms, so that the humbler marine life is the ultimate provender of those food-fishes which supply so large and increasing a portion of the food of mankind.

Millions of the planctonic creatures are either microscopic in size or so transparent as to be invisible ordinarily. However a pretty experiment demonstrates the presence of some of these tiny forms. It consists in placing a glass dish full of clear sea-water in a dark room and then allowing a beam of light to fall upon it. Just as such a beam will show the motes dancing in air it will show thousands of shining particles which are really living beings dancing in the water.

The planctonic creatures are divided into two great classes, those which are pelagic, i. e., the ones whose whole life, both larval and adult, is spent floating in water, and those which are attached to the submarine soil during part of their existence. The latter are found especially in littoral waters. Marine plancton, which is of course far more important than the fresh water plancton, though this also exists in great quantities, is also divided into the oceanic, found in the deep seas, and the neritic, which is found near shore, that is, above the continental plateau.

Some good work has been done in this country in the study of plancton, especially on the coast of California, but the great authority on the subject is the well-known scientist Dr. Richard of the Marine Museum of Monaco. We are indebted for the facts in this article chiefly to the researches of Dr. Richard as reported in a recent encyclopedic article in *Larousse Mensuel*. The first method of collecting plancton for study was by a net much resembling an ordinary butterfly net attached to a line instead of to a pole and trailed behind a boat. But the resistance of water is so much greater than that of air that the fine silk gauze or bolting-cloth used for the net interfered with the filtering of the water at even a moderate rate of speed. Hence Dr Richard modified the shape of the net by making its length greater and its orifice smaller This increases the surface of filtration and the plancton collects in the end of the long cigar-shaped net and is examined at leisure in the laboratory.

A very important point is to test the amount of plancton in a given quantity of water. This is accomplished by emptying the plancton into a graduated beaker. At the end of several hours it has collected in the bottom of the beaker and its bulk is indicated by the figure at which it stands. Thus an estimate is readily formed of the comparative alimentary richness of any given area of the sea, information of great practical value in the fisheries industries. But it is likewise highly important to know the nature and habits of the species found, since some of these form the favorite food of sardines, lobsters, crabs, cod, herring, or other of the chief food fishes, and a knowledge of their habits and their habitats is immensely useful to the fisherman who would make a full haul.

Such examination of species is chiefly conducted in the laboratory, but preliminary work can be done on board ship by an apparatus invented by Dr. Richard, which consists of a glass dish filled with the water to be examined, a lense, a mirror inclined at an angle of 45 degrees, and a white screen on which the images of the tiny creatures are thrown; the apparatus is completed by a device which compensates the rolling of the vessel.

It is very beautiful to see how exquisitely the creatures which compose the plancton are adapted to their peculiar mode of existence. The most striking feature of this adaptation is the crystalline transparence of most of them which makes it difficult to distinguish them from the water which surrounds them. "It is very curious to see muscles, cartilages, and teguments which resemble glass without being altered in their functions; they can scarce be distinguished from the water except by mingling therewith some reagent which kills them and coagulates and renders opaque their tissues." A similar modification is the clear blue tint of many of the pelagic creatures which live near the surface. This is a very characteristic case of protective coloring, and is never found in specimens found at great depths where the sun does not penetrate.

Since the tissues of these animals are infiltrated with water they have a density approximately that of the water by which they are surrounded; but since even their very slight excess of density would carry them down sooner or later they are provided with special compensating apparatus. Sometimes they have fins whose force can be exerted in a direction contrary to that of gravity; or they may have floats consisting of a drop of oil or a bubble of air in a contractile sac. Still others have appendages shaped like paddles, or like feathers, whose surface resists the downward pull.

"All these creatures, to diminish their density, have eliminated from the organism the heavy parts—the thick bones, compact shells, resistant carapaces which are borne by their congeners of the littoral and the bottom. Thus one observes very curious creatures among them, whose viscera occupy a comparatively small part of the gelatinous mass of their transparent bodies."

Very often the planctonic animals which live several hundred meters below the surface have developed enormous eyes; their antennae and their claws are elongated also, and the minute organs of sensation which cover their bodies are hypertrophied. The pelagic animals which live at great depths develop "telescopic" eyes, i. e., they are cylindrical instead of globular. This is only found at such depths that only the ultra-violet rays of the solar spectrum can penetrate. Another notable feature is that the otocyst, the organ which replaces the ear in inferior animals, is highly developed and acts as an organ of equilibrium.

Their fecundity is, of course, enormous and the ship "National" on one occasion observed a great swarm or shoal of one variety floating on the surface and no less than 260 kilometers long. Obviously such a huge mass of tempting food material will attract hungry schools of fish, hence it is of interest to learn what conditions the presence or absence of various kinds of plancton in any given locality. It has already been observed that the composition of the plancton in any place varies at different seasons or even different times of the day. Thus they will descend when the surface of the ocean is agitated for their bodies are too delicate to bear violent motion. Rain also drives them down, since they are not fitted for contact with fresh water. Some cannot bear light and fly from the approach of daylight, while others execute the inverse movement Hence the "catch" of plancton varies according to whether the net is cast by day or by night. Some varieties appear only at certain seasons of the year, which fact may be due to variations in the temperature of the superficial layers of the water; and still others appear only at intervals of several years, for reasons as yet unknown. Such facts as these are of prime importance to the fisherman, and it is hoped that when these movements of plancton are fully understood much of the present uncertainty in the fisheries industry may be eliminated.

Most of the plantonic plants are microscopic algae, a large percentage being composed of immense shoals of diatoms. These are most abundant in the cold waters of the temperate and the polar seas. It has been estimated that a cubic meter of water off the coast of Iceland contains 5 billions of them Another common species is the peridinians, which are ranked as plants because of the carapace of cellulose, though some of their characteristics relate them to the protozoa.

Among the pelagic protozoa special mention is due to the *foraminifera*. These secrete a tiny shell of calcareous matter, through whose apertures extend the long filament of the animal's gelatinous body. When the animal dies this shell is no longer buoyed up and slowly sinks. More than 150 million square kilometers of the bottom of the sea are thickly carpeted with a mass of these tiny shells. Nearly two-thirds of the bottom of the Atlantic is covered with them. A curious fact is that they are not found below 5,000 meters in depth, because their substance being slightly soluble in water is dissolved by the time it has reached a certain depth. It is of such deposits as these that our sedimentary rocks are made. Similar deposits are made by the species radiolaria, but as their skeleton is silicious it is less soluble and is therefore found in very deep areas of the Pacific ocean. The common phenomenon of phosphorescence in salt water is due to other species, and persons who take sea-baths at night often observe shining flecks like scraps of phosphorus clinging to their garments.

Other varieties are the *coelenters* and the *siphonophores*. Also the larvae of the *echinoderms* and of *eels*. Besides these may be mentioned certain molluscs. *Crustacea*, etc., are abundant both in fresh-water and salt-water plancton. "Their small species, especially the *copepods*, swim in huge shoals. They are found in all seas and form the basis of the animal nutriment of marine animals; it is these above all on which the sardine feeds and the movements of shoals of sardines follow those of *copepods* and *peridinians*. Doubtless the presence of the latter is dependent on varying conditions of temperature, salinity, etc., and the apparently recondite labors of the marine geologist may prove of invaluable commercial aid, another argument for the liberal support of pure science.

Much remains to be done in this vast and fertile field of investigation, especially in the study of pelagic plancton both on the surface and in the depths of the sea. In closing, a word must be given to the special net devised by Dr. Richard for obtaining deep sea plancton. This consists of a square frame composed of iron rods, each 4 meters long. To these are attached triangular pieces of cloth of such mesh as is desired, from that as coarse as canvas to that which contains 6,000 apertures to the square centimeter.

These triangles meet at a common apex, thus forming a huge pyramid. This is lowered by a steel cable operated by steam-power. To fish at 6,000 meters the cable must be 10,000 meters long to allow for its oblique line when the boat is moving. When the boat stops the net is drawn up very slowly and carefully. At 5,000 meters depth the column of water above the top of the net would have a volume of 80,000 cubic meters, and every drop of this vast amount must be filtered through the meshes of the net. The resultant catch contains all the plancton existing in that vast bulk. Devices have also been invented for securing the catch from a given layer at a given depth, shutting off the top layers, but as yet have worked imperfectly.

Oil Filters

According to the *London Times* a form of oil filter and drier designed by the British Thomson-Houston Company, of Rugby, is specially intended for the purification of oil used in transformers and other high-tension oil-filled apparatus, though it can also be used for the treatment of many other liquids as well as heavy viscous compounds, the latter being preferably warmed. The importance of dryness in transformer oils is illustrated by the fact that the quantity of water present must not exceed 0.001 per cent in order to obtain a dielectric strength of 40,000 volts in the standard test (0.1 inch between disks 1 inch in diameter), as required for high-tension work. Fine dust, especially metalic, is almost as effective as water in reducing the dielectric strength, and it is, therefore, necessary to remove any sediment which may result from long continued heating, in order to preserve the normal viscosity of the oil and to prevent incrustation of the interior parts of the transformer and the clogging of the oil channels. In the B. T. H. arrangement the oil is pumped under a pressure of 25 to 100 pounds per square inch through layers of pure white blotting paper made principally from wood pulp and supported in a suitable filter press. Most of the solid matter is caught by the first layer of paper, while the water is retained by capillary action in the paper, the capillary attraction between the paper and the water being greater than between the paper and the oil. The presses are made in two standard sizes, one 7-inch, with 14 chambers, having 7 square feet of filtering surface, and the other 12 inches, with 20 chambers, having 30 square feet of surface. Special electric ovens have also been designed for drying the filter paper. The effects of filtering are illustrated by a test carried out on oil which had been in use for about 10 years. Before filtration it broke down at 1,800 volts, with electrodes of 0.05 inch apart; after one filtration it broke down at 10,200 volts; and after a second filtration it withstood 20,000 volts without breaking down.

Importance of Aluminium

In a paper read before the Junior Institution of Engineers, in England, E. N. Munro calls attention to the increasing importance of aluminium. He states that for electrical purposes aluminium was fast becoming common. Overhead transmission lines constructed in aluminium showed a great saving over equivalent copper lines, a saving of as much as 10 to [illegible] per cent being effected, depending on the size and [illegible] of the system [illegible]. The commercial [illegible] of aluminium became [illegible] when Hall in America [illegible] and Heroult in France produced the metal electrolytically in [illegible].

The Function of Enzymes*

Products of Living Cells That Affect the Chemical Operations of Living Matter

By Samuel C Prescott

The study of the chemical or physiological activity of cells, whether of microbes or of men is at once one of the most interesting and one of the most difficult problems of the biologist, for it seeks to disclose the secrets of life processes How does a disease germ produce its poison, or a yeast cell bring about its characteristic fermentation? How do we carry on those transformations of food material by which beefsteak and bread and butter at once become available sources of energy and matter for our living machine? How does a potato manufacture starch in its leaves transfer it to the growing tubers and there store it up for future use?

In each case by means of enzymes which we may define as the tools of cells and the reagents by which the chemical reactions of cells of all kinds are effected

The term ferments' was first used early in the nineteenth century by Schwann and Berzelius Afterwards the word was used somewhat indiscriminately, meaning either a micro-organism of fermentation or a chemical substance which in some way was related to living cells To distinguish between these the physiologist Kühne suggested the term enzyme to designate the digestive ferments such as pepsin trypsin and ptyalin The word has now been universally accepted as the name of a group of chemical bodies products of living cells which have the peculiar property of effecting the chemical operations of living matter but which do not enter into the final products of these reactions

Chemistry cannot produce enzymes for they are found only as the products of protoplasm of living cells and it makes no difference whether we are dealing with the ultra-microscopic bacterium or the giant redwood or the whale, the chemical activities are due to enzymes Furthermore the same kind of enzyme may be produced by organisms of widely different character as for example the trypsin of certain bacteria of the carnivorous plants like the Venus Fly Trap and of the human intestinal tract

Since the variety of chemical processes carried out by living cells is large in number it follows that the number of enzymes is legion Even the number produced by a minute bacteria cell hardly visible with a high power of the microscope may be several while with organisms of highly specialized form and physiological division of labor the number is greatly increased In man at least fourteen are known to be developed in the alimentary canal and to take part in the process of digestion while if we added all the other chemical changes which may be elaborated in the body as a whole, our catalogue would be greatly increased Moreover we may assume that there are many enzymes which are still unknown for the enzymes may be intra-cellular that is acting only within the cell as well as extra-cellular or extruded outside the cell and so possibly capable of detection The positive knowledge of the action of intra-cellular enzymes is still very meager although when Büchner discovered zymase and a method for its preparation in 1897 the first great step forward in their study was made

What an enzyme really is cannot be exactly stated An enzyme is known only by its reactions By their works ye shall know them is essentially true in the ferment world We cannot even tell their composition or to what class of chemical substances they belong for they have never been obtained in pure condition It is generally assumed however without proof that enzymes are protein-like in character In spite of this indefiniteness and the elusive character of these bodies certain general properties regarding them have become known and on these points all enzymes behave in like manner, although differing distinctly from other chemical substances

We may thus regard enzymes as forming a special and peculiar group of chemical compounds differing in certain ways from other substances, and especially in their relation to the law of mass action as shown by the great disproportion between the amount of the active substance and the amount of material changed. A good example of this is rennet, which it has been stated can coagulate from 800,000 to 800,000 times its weight of casein, without being used up. All enzymes possess the same characteristic but not necessarily in the same degree. The activity is largely dependent upon the physical and chemical conditions of the environment. Thus very slight changes in the reaction of the medium on which an enzyme is acting may control very largely its power, or make the difference between high efficiency and practical inactivity. Some enzymes require neutral solutions for action others are most vigorous in slightly acid or slightly alkaline media

Similarly temperature may play a very important part in the control of enzyme reaction In this respect these substances behave closely like living cells and like certain kinds of proteins Each enzyme has a maximum a minimum and an optimum temperature of activity just as microbes have and like these if heated above the maximum will be rendered inactive and finally destroyed This thermal death point as it may be called is very near the coagulating point of albumin and not far from the death point of most vegetative bacteria Another similarity to the proteins lies in the fact that both enzymes and albumins are precipitated by concentrated salt solutions such as ammonium sulphate by alcohol and by salts of heavy metals Furthermore they may be more or less completely mechanically precipitated with flocculent or bulky precipitates as by use of phosphoric acid and lime water Certain poisons may also inactivate enzymes Substances which kill living cells like formaldehyde hydrocyanic acid or mercuric chloride will in general kill enzymes provided the solutions used are strong enough and sufficient time is allowed for the destructive action The enzyme has a somewhat greater resistance than has the living cell but the difference is one of degree rather than of kind In fact so closely do enzymes correspond to micro-organisms in behavior toward physical agencies poisons etc that we use the same terminology in discussing them and speak of the poisoning or killing of the enzyme Other substances such as toluene chloroform and a few others permit enzyme reaction but restrain the activity of living cells thus giving a differentiation of great value in studying them

Enzymes also have many properties in common with the *toxins* and so far as body reactions go seem to belong to the same class of organic compounds When a toxin is injected in small amount into the body certain chemical changes are set up and there is soon formed a so-called antitoxin which neutralizes or inactivates the toxin Similarly the action of enzymes upon the tissue of the living body is effected by the secretion of anti enzymes and the injection of foreign proteins into the body may be followed by the manufacture of a precipitin which will precipitate that particular protein and no other This specific action is characteristic of enzymes and toxins as well as of proteins In view of the fact that enzymes and toxins are like proteins the products of living cells it may not be strange that this similarity is found However we are not able to say that enzymes are protein in character but rather that they are found in association with proteins The purest enzymes yet prepared do not give protein reactions Moreover mineral salts seem essential for their action

We may explain the mechanism of fermentation and putrefaction changes on the basis of the enzymes produced by the inciting organisms for in recent years it has been shown that the enzymes carefully prepared and fed from living cells will carry on the same changes with almost mathematical precision In yeast for example Büchner found within the cells an enzyme which could only be extracted by grinding with fine sand and subjecting to enormous pressure but which when thus obtained produced alcohol and carbon dioxide from sugar in exact accordance to the chemical equation which had long been used to represent the fermentation Thus it was shown that intra-cellular enzymes exist and we now believe that many processes taking place in living cells—perhaps all the processes—are the results of enzyme activity

Since the chemical nature of enzymes is so largely unknown, we can classify them only by their action on various compounds It is possible however to group them into the four classes of *hydrolyzing* or causing the addition of water to certain substances Most enzymes acting on carbohydrates are of this class So also are those that affect fats and the majority of those producing known proteolytic changes These are best represented in the processes of digestion A second group are the *Zymases*, or those producing the splitting of bodies into simpler cleavage products without any hydration The alcoholic fermentation is the best known of this class

The remaining two classes are the *oxidizing* and *reducing* enzymes, producing the types of change implied Of the former, the production of vinegar is a familiar example, alcohol being oxidized to acetic acid by an oxidase produced by the acetic bacteria Such familiar changes as the darkening of freshly cut surfaces of fruits (apples) or the quick change of color when mushrooms and toadstools are broken also belong to this category The reduction processes are of enormous variety in nature both in plant and animal life While typically distinguished by the reduction of hydrogen peroxide to water and oxygen these katalases as they are called may also reduce sulphates nitrates and various coloring matters as well as other compounds Upon the activity of enzymes may depend all the complex series of changes oxidations reductions synthetic and analytic changes which characterize the process of growth and decay renovation and destruction in the cell and in tissues The phenomenon on intra-cellular fermentation seems to be closely linked with enzyme activity and the building up and breaking down of protoplasm itself is intimately connected with intra-cellular changes and energy liberation

There is reason to believe that some enzyme actions are like organic chemical reactions reversible Thus maltase will split maltose into two moleculars of dextrose under the ordinary conditions of action If however we add maltase to concentrated dextrose solutions a small amount of maltose (or isomaltose a similar sugar) will be formed the reaction proceeding until a certain equilibrium is established This has not been demonstrated for all enzymes and some eminent authorities divide enzymes into two classes only one of which is catalytic and capable of synthesizing as well as splitting substances while in the other no trace of synthesis has been observed

On the subject of the origin of enzymes and the causes stimulating their activity many interesting observations have been made Some enzymes are produced by cells in such form as to require no further aid to render them active Others require the presence of a specific substance known as an activator The pepsin of the stomach is produced by the cells of the gastric glands as a zymogen called pepsinogen which under the influence of the hydrochloric acid produced at the time the stomach is functioning becomes changed to pepsin We do not know how the enzyme and the acid are associated but we know that the latter is necessary for the production of pepsin and also for its action Bayliss has described another instance in which the activator itself, enterokinase acts as an enzyme upon the zymogen trypsinogen thus producing trypsin but without entering into the actual formation of the finished enzyme—trypsin If this view is correct, we have in effect one enzyme bringing a second into existence In other instances activation is effected by metals as in the laccase the oxidizing enzyme of the lac tree of Asia which requires manganese or by salts such as phosphates as in certain alcoholic fermentations

In spite of the apparent lack of exact knowledge of the composition of enzymes and of all their activities we find in this group of substances agents which are of direct and certain application to industrial processes Breadmaking brewing cheesemaking certain phases of tanning as well as the preparation of lacquers and castor oil are a few of these applications

Here is a field of great promise and infinite interest sure to yield results if investigated patiently and consistently by the scientist who combines a deep knowledge of organic chemistry with an intimate acquaintance with cell behavior and activity and this field of bio-chemistry is sure to find greater favor in the immediate future

A New Telephone Receiver

At a recent meeting of the Royal Society a new form of telephone receiver was exhibited that was about the size of a half inch section of a lead pencil The specimen shown was made at the laboratory of the University of Utrecht, under the supervision of Prof. Zwaardemaker and had been in use for several months without showing any signs of deterioration It is stated that in the new instrument the electro-magnet and diaphragm of the ordinary telephone are eliminated, and for them is substituted a loop of very fine platinum wire within a small cover pierced with a minute hole. As currents pass through the wire they cause small increases and decreases of heat and the consequent expansions and contractions of the surrounding air become evident as sound Owing to the smallness of the receiver it can be put in the ear and sounds are not confused by extraneous noises while the faithfulness with which the intonations of the voice are transmitted is remarkable. The whole apparatus is more compact than the ordinary instrument and the cost is low

Roentgenology in War

How Modern Science is Brought to the Field of Action in War

Very soon after the Roentgen rays became known attempts were made to apply this branch of diagnosis to wounds. Such experiments were tried as long ago as 1896 by the Italians in the Abyssinian campaign; then in 1897, during the Greco-Turkish war, Küttner made use of the Roentgen rays in examinations at the Yildiz hospital at Constantinople, as did also Abbott, who was surgeon on the Greek side, at Phalerus. After this work was done on a small scale in the colonial wars of the English, and finally Roentgenology was established on a much stronger basis through its wide use in the Spanish-American war, 1898-1899, and in the Boer war, 1899-1900. The Herero revolt also gave occasion for its employment in the treatment of wounds. Roentgen

rays were much used in the Russo-Japanese War, while in the Balkan war there came into active service the most advanced types of portable Roentgen apparatus.

An interesting account of the equipment of a military Roentgen outfit, intended for use in the field, is given in *Die Umschau*, by Surgeon-Major Dr. Strauss, head of a Roentgen laboratory, who tells us that a field Roentgen apparatus is decidedly complicated in its make-up. It must be transportable, should meet all the requirements of modern Roentgenology, and requires a large supply of photographic materials as well as a large amount of additional supplies for the taking of photographs, throwing light, etc. It must also have with it a goodly number of extra parts of the apparatus, so that to carry the whole outfit a very large wagon is necessary, as is shown in the cut of the field Roentgen wagon used in the German army. This wagon contains an inductor with a spark 45 centimeters long, which is driven by a current of 20 amperes strength and 65 volts pressure. This current is interrupted by a Wehnelt contact-breaker, the working of the current being regulated by a switchboard. Besides this apparatus the supplementary parts mentioned above are also stored in the wagon. In all field Roentgen outfits the great difficulty is the source of the current. Ordinarily no dependence can be placed on the chance of connection with an electric wire, especially in the eastern seat of war. The current necessary must, therefore, be generated. The only simple way in which this can be done is by a dynamo driven by a benzine motor.

None of the attempts to get around this difficulty have proved really satisfactory. The entire running of the apparatus would be far simpler if it were possible to generate a sufficiently strong current by means of the condenser. Up to the present time, however, the experiments to this end have not been as successful as required for practical use, although Wommelsdorf's labors in this direction have brought the problem nearer solution. The scheme to replace the dynamo and the benzine motor by accumulators must also be abandoned, for after the accumulator is discharged the recharging in the field is an uncertain matter. As a result of all these factors a field Roentgen outfit represents a heavy weight, and consequently there are definite limits to its use. A benzine motor being necessary for the generating of a current, the thought naturally occurred to work out the entire field Roentgen apparatus as an automobile, and thus to unite in ingenious manner the means for generating a current and for moving about. This idea, which at the present time the French have put into practical use, was debated long ago by the Germans, who finally rejected it. The peculiar conditions of a campaign on the eastern border in winter would make the use of an automobile very uncertain, consequently a field Roentgen automobile would frequently be condemned to stand idle. So on this account the Germans decided to place the military Roentgen outfit in a wagon drawn by horses, the wagon externally being somewhat similar to an ambulance.

As regards the making of Roentgen-ray examinations in the field, says Dr. Strauss, the many experiences of the campaigns first mentioned show that the Roentgen process is only applicable when it is possible to take definite medical measures. To send the military Roentgen wagon to the spot where first aid is given to the wounded, or to the field hospital, which is often moved five or six times, would be nonsense. All demands that this should be done come from those who neither understand military conditions nor the Roentgen process. Examinations with the Roentgen rays can only be made where quiet and settled conditions prevail. Anything so costly to procure as a field Roentgen outfit should not fall into the hands of the enemy or be destroyed when troops are obliged to fall back. It should also be remembered that the use of the Roentgen rays is a very precise process, and that rough work in the open air without the equipment for a dark room, etc., cannot be thought of. Consequently, these outfits are distributed among the military hospitals. There, where there is quiet and security, the Roentgen process accomplishes positive results.

The chief value in diagnosis of investigation by the Roentgen rays is in the finding of splinters of shot that have remained behind in the body, in the recognition of severe inflammatory conditions in the bony structure, as the dying of some part of a bone or suppuration, and in the determining of injuries to the skull. This naturally brings up the entire question of the value of diagnosis by these rays in internal medicine, as well as, to some degree, of the curative power of the Roentgen rays.

The number of Roentgen outfits taken into the campaign by the German army is relatively large, and the equipment is so complete that salutary work is possible in those parts of the field of war away from ordinary means of communication.

Baskets for German Ammunition

One of the many details developed by the German army is what appears to be a new idea in the rapid handling of ammunition for all classes of artillery. In shipping shells, when they are being sent to the front, it is not customary to box or crate them, and they are by no means easily handled on account of their construction, especially the larger sizes. Moreover, if not protected in some way they are liable to injury. To meet these conditions the Germans have made baskets of various sizes, according to the size of the shell to be handled, the largest size containing a single projectile. Other baskets are made in various shapes, with receptacles for shells and cartridges. All the latest patterns of baskets for transporting shells have eight strips of hard wood, four on the outside and four on the inside, extending from the top to the bottom of the basket. The outside strips protect and strengthen the basket, and the inside ones keep the shell in place. Two strips of canvas belting are attached to a circular leather bottom upon which the shell rests, the outer ends of the strips being fastened together, forming a hold by which the shell is lifted from the basket. Baskets are made in various sizes, some with divisions to accommodate cartridges. The baskets are kept filled with shells and cartridges at the artillery depots, ready for quick shipment to the front. The baskets protect the shells and explosives from contact with hard substances as well as facilitating their rapid handling. Within the last few years upward of 1,500,000 baskets have been made for the German army, and before the war large numbers of baskets were sent to Austria and Turkey.

Effects of Vacuum on Performance of Steam Turbines

In a paper by Mr G Gerald Stoney read before the Institution of Mechanical Engineers discussing the effect of variations of vacuum on steam turbine installations on land and at sea and published in the *London Times* the author said

The degree of vacuum which gives the same velocity ratio at the exhaust end as throughout any given turbine is the vacuum under which the best results are obtained consequently a turbine designed for 29 inch vacuum barometer 30 inches requires more rows of blades or wheels than one designed for 27 inches the number of rows or wheels on a given diameter in each case being proportionate to the British thermal units available in the range between the initial and final pressures and temperatures through which the turbine works There may however, be considerable latitude in the velocity ratio at the exhaust end without seriously affecting the available economy

GAINS DUE TO HIGH VACUUM

The percentage gain due to vacuum depends on the steam conditions, being much more with low-pressure than with high-pressure steam and the gain in British thermal units available is almost independent of the steam conditions In other words for each degree Fahrenheit that the temperature due to the vacuum is reduced there are approximately 1 5 more British thermal units available These gains due to vacuum are wholly attainable when the turbine can be suitably designed but for high-speed large output land turbines allowance must be made for increased terminal losses

For example in a 3 000 kilowatt land turbine at 3 000 revolutions per minute, with an initial pressure of 175 pounds 150 deg Fahr superheat and a vacuum of 29 inches the consumption will be about 121 pounds per kilowatt-hour and the steam per hour will be 36 000 pounds or 10 pounds per second The volume at exhaust allowing for condensation will be about 6 000 cubic feet per second With present materials available it is not in general customary to go above about 550 feet per second for the mean velocity of the blades at the exhaust end giving a mean diameter of 42 inches and as the blade height in practice cannot be more than one-fifth of this or 8 4 inches the area of the annulus is 7 7 square feet The velocity of the steam leaving the blades through the restricted area will then be 780 feet per second and involve a loss of 12 British thermal units assuming that the velocity ratio and angle of the blades is such that the steam leaves them axially as it should to give the minimum loss Even under these conditions however there is still a gain of 6½ per cent between 28 inches and 29 inches vacuum For still larger powers however, these effects become more pronounced until conditions are eventually reached in this class of turbine having a highly restricted exhaust end when an increase in vacuum causes no gain It is the constant aim of designers to increase the limiting vacuum by using higher blade-speeds, and enabling an exhaust end of larger dimensions to be employed and this is undoubtedly a direction in which increased efficiency in large power high-speed turbines is to be found

The effect of increased blade-speed is very marked as for a given vacuum the reduction in available gain varies inversely as the fourth power of the blade-speed since as the blade-height cannot well be more than one-fifth of the mean diameter of the blades the area at the exhaust will vary as the square of the diameter or as the square of the mean blade velocity Therefore the longitudinal velocity varies inversely as the square of the mean blade velocity or the British thermal units lost inversely as the fourth power Of course, the reduction can be halved by adopting a turbine with double flow at the exhaust, but this often introduces complications although many highly economical land turbines of large power have been designed on these lines Something can also be done by shaping the exhaust suitably so as gradually to reduce the velocity of the steam on leaving the blades

DIRECT-COUPLED AND GEARED TURBINES

Direct-coupled marine turbines especially from considerations of weight and space, are often bladed so as to give uniform velocity ratio at full speed with about 26 inches vacuum, and from various causes many land turbines have been similarly bladed In turbines so bladed and with ordinary steam pressure, it has been found by experience that the gain per inch of vacuum at full load is, between 26 inches and 27 inches, 4 per cent or 12 British thermal units, between 27 inches and 28 inches, 5 per cent, or 17 British thermal units between 28 inches and 28½ inches, 6 per cent, or 22 British thermal units and between 28½ inches and 29 inches 7 per cent, or 27 British thermal units. In the turbines so bladed and at constant speed, as in land work the velocity ratio at the exhaust end would automatically become at half-load uniform with the rest of the turbine at about 28 inches, and for quarter-load at about 28¾ inches. Hence in general the theoretical gains will be [illegible] obtained [illegible] blade

Geared turbines can stand and should be bladed for high vacuum and the blading should be for nearly the highest vacuum obtainable in the waters in which the ship trades as there is but little loss by running a turbine bladed for high vacuum at a lower one For example it should be bladed for 28½ inches to 29 inches the vacuum obtainable in home waters and the like and not for 27½ inches to 28 inches which will be the vacuum obtainable in the tropics with a good condensing plant In such turbines the full theoretical gain due to vacuum will be attained at full speed while at half speed and one-eight power the gain due to increased

3 Side view of interior of a Roentgen field wagon
J inductor *M*, motor *P* photographic apparatus *b* switchboard

vacuum will be somewhat more than that at full speed

In most cases blading a geared turbine for high vacuum as compared with low vacuum adds very little to the weight and generally only necessitates the exhaust end being made somewhat larger It is very important that the exhaust between the turbine blades and the condenser should be free and should be unrestricted so that the loss of vacuum between the last row of blades and the steam space in the condenser should be a minimum This applies to all classes of turbines It is equally important that the loss of vacuum between the steam space in the condenser and the air-pump suction should also be a minimum In other words given a condenser and an air-pump of the highest efficiency the difference in vacuum between the air-pump suction and exhaust end of the turbine should be reduced to an absolute minimum

TREATMENT OF EXHAUST STEAM

In a complete installation, whether land or marine there are many other factors besides the turbine to be taken account of As increase in vacuum is associated with a corresponding lower temperature of condensate it follows that if the vacuum is raised and the condensate is delivered to the boiler at the same temperature at which it leaves the condenser either the quantity of steam generated in the boiler per unit of coal is decreased or the quantity of coal per unit of steam generated is increased In practice, however both on land and at sea the condensate is invariably heated either by the waste gases from the boiler or by the exhaust steam from the auxiliary engines, or by both Land installations usually include an economizer in the boiler uptake, and the practical requirements in such a case is that, in order to prevent sweating on the tubes the feed water should be delivered to the economizer at a temperature of about 120 deg Fahr But even at the highest vacua there is usually sufficient exhaust steam from the auxiliaries to raise the condensate to this temperature so that such a system represents the highest economy attainable with any given plant

Marine installations present a different problem by reason of the large quantity of exhaust steam available from the auxiliary engines and it may here be noted that the heat in exhaust steam is used to the greatest advantage possible when it is re-delivered to the boiler with the feed water It follows that in order to attain maximum economy on shipboard the entire exhaust from auxiliary engines should be condensed by the feed water A perfect installation from this point of view would be one in which the turbine works under the highest attainable vacuum with efficiency and in which the exhaust steam is maintained at such pressure as will enable its heat to be wholly transferred to the feed water In fact the economic pressure for the auxiliaries to exhaust at is that in which the whole of their exhaust can be condensed by the feed Obviously there should be no surplus exhaust and if there is a surplus it should never be discharged into the main condenser because of the highly prejudicial effect of oil on the heat-transferring efficiency of the condenser tubes and on the vacuum

The direction in which progress is to be made on marine turbine installations would therefore appear to be (*a*) High vacuum turbines (*b*) high efficiency condensing plant (*c*) economical auxiliaries and (*d*) efficient exhaust-steam feed heaters In some cases where there is a surplus of auxiliary steam it is turned into the low pressure turbine Here there is an apparent partial recovery of the loss but in practice this arrangement has the defect of fouling both the turbines and the condenser with oil and reducing their efficiency so that the entire power of the turbine may easily be reduced to a far greater extent than it can be increased by the use of such surplus steam If the steam is used in this way it should be very carefully filtered

CONDENSER DESIGN

The effect of reduced conductivity of the condenser such as is caused by air is much more at high rates of condensation than at low showing that the effect of a faulty air-pump or dirty condenser is much more when the rate of condensation is high Approximately also the loss of vacuum below that theoretically obtainable depends only on the rate of condensation and on the amount of air insulation and not on the quantity of circulating water and always assuming a condenser free from oil on the outside of the tubes and scale on the inside there is not much use in having more circulating water than about 60 to 80 times the steam condensed at full load in home waters and the tropics respectively Money put into a condenser of ample size is money well spent Ample surface also gives a good margin to allow of the condenser getting dirty or for overloads

Fire-resisting Wood

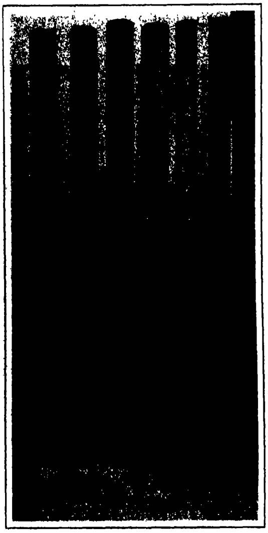
The British Fire Prevention Committee have issued a report on a test they carried out on a partition made of wood which had been impregnated by the Oxylene process with the object of making it fire-resisting The partition measured 10 feet by 9 feet, and its head sill side posts and intermediates were constructed of 2 inch by 1⅞ inch deal each side being covered with ⅝ inch grooved tongued and beaded boarding in 5-inch widths It was submitted for 45 minutes to temperatures that rose to 1 630 deg Fahr and then water was pumped upon it from a steam fire engine According to the official observations smoke appeared through the joints on the outside after 38 minutes and scorching was noticed at several joints two minutes later while after 44 minutes a glow was visible at four joints Water came through several of the joints when at the end of the test the hose was turned upon the partition which however remained in position Although the resistance of the woodwork did not last long enough by a few minutes to enable the partition to be classed as affording temporary protection under the committee's standards a note prefixed to the report states that the test demonstrates that the impregnating process employed has a retarding effect on combustion and that timber so treated should be a valuable addition to the stock of fire-resisting materials The process consists in submitting wood to a course of steaming vacuum and pressure whereby the sap water air and moisture are removed and replaced by a chemical solution which is preservative antiseptic, non hygroscopic and non-corrosive The water of this solution is then evaporated by placing the wood in drying kilns the chemicals being left embedded throughout the fibers of the wood in minute crystal form On the application of heat the crystals expand and form a glassy coating to the wood this coating excluding the oxygen of the air and preventing combustion.—*London Times*

Iron Manufacture by Electrolysis*

Properties and Industrial Applications of the Product

By L. Guillet

The industrial manufacture of iron by electrolysis is a problem which has engaged attention for many years, but it is only within the last year that it has entered the practical stage. In principle, the method consists in the use of a revolving cathode and a neutral solution of iron salts, maintained in the neutral state by the circulation of the liquid over the surface of the iron. The bath also receives periodic additions of a depolarizing medium, such as oxide of iron, the object of which is to eliminate, at least in part, the hydrogen deposits on the cathode, which injuriously affect the material if present in too large a quantity. By these means it is



Commercial tubes of electrolytic iron.

possible to work with a current of high density (1,000 amperes to the square meter), and an iron of excellent quality is obtained. The process is applicable either to the production of very pure iron, which can compete with the best iron and Swedish iron, or to the direct manufacture of tubes and sheets in the finished state. It has emerged from the laboratory stage, and is now being put into operation on an industrial scale.

PROPERTIES OF THE METAL.

Using any pig iron in solution, an electrolytic iron can be obtained of the following average composition, after removal of the gases by annealing:

	Per Cent.
Carbon	0.004
Silicon	0.007
Sulphur	0.006
Phosphorus	0.008

At the present time it is possible to guarantee phosphorus lower than 0.010 per cent. With a density of current of 1,000 amperes per square meter, the yield per kilowatt-year is 2 tons of metal, including the cost of current for the accessory services, particularly for the rotation of the cathodes.

The material in the crude state, that is, in its state on removal from the electrolyte bath, is hard and brittle. In fact, two effects are produced in the process of manufacture. The metal is interstrained and has absorbed gases, particularly hydrogen. On heating in vacuum between 800 and 1,100 deg. Cent. for four hours, and then raising it to the neighborhood of 1,400 deg. Cent. for a further two hours, Sir Robert Hadfield found that 34 grammes of the iron had a volume of 4.3 cubic centimeters and yielded 28.8 cubic centimeters of gas of the following composition:

	By Volume. Per Cent.	By Weight. Per Cent.
Hydrogen	18.8	66.8
Carbon monoxide	7.4	23.7
Carbon dioxide	0.2	0.7
Nitrogen	2.2	7.6
Oxygen	..	..

The presence of carbon monoxide is somewhat noteworthy. On its removal from the electrolyte, the iron is very brittle, and has a Brinell hardness of 193, using a ball of 10 millimeters diameter under a load of 3,000 kilogrammes. The micrographic examination reveals an entirely characteristic structure, consisting of innumerable fine needles, very much resembling martensite.

After annealing for two hours in magnesia at 900 degrees, the iron shows a Brinell hardness of 90. The micrographic structure is perfectly normal. The tensile test gives a breaking strength of 30.9 to 32.8 kilogrammes per square millimeter, and an elongation of 40.2 to 42.1 per cent in the direction of the axis of the tube. Further, the annealed tubes, when subjected to compression tests, can undergo deformation to an extraordinary degree without a sign of any fracture, as shown in one of the illustrations.

INDUSTRIAL APPLICATIONS.

The industrial applications of electrolytic iron fall into three principal categories: (1) the direct manufacture of tubes; (2) the direct manufacture of sheets; (3) the preparation of pure iron as a raw material intended for fusion. There are various other uses of less importance, such as the preparation of rods of very pure iron for autogenous welding.

Tubes.—The manufacture of tubes is being proceeded with on an industrial scale by the Bouchayer & Viallet Company, whose installation is capable of turning out 100 tubes per day. The current practice of this company is to manufacture tubes 4 inches long, 100 to 200 millimeters in diameter, with a thickness of 0.1 to 6 millimeters. Some of these are shown in one of the illustrations. As is well known, all present methods of manufacturing tubes present certain insurmountable difficulties when it is desired to obtain regular thicknesses of less than 6 millimeters. As a general rule, in the products obtained the thickness of the wall is far from constant. With the electrolytic process it is possible to obtain the most satisfactory regularity whatever the thickness, diameter, and length of tube.

The tubes will withstand considerable pressures. Thus, a tube of 100 millimeters diameter and 0.75 millimeter thickness, subjected to 1,200 pounds per square inch, underwent a permanent deformation of a regular character, as if squeezed in a press. Another specimen of the same tube was exposed for two and a half months to a temperature of 120 degrees in a boiler. It was then tested to 1,200 pounds per square inch, but no trace of fracture was perceptible.

Sheets.—The manufacture of sheets is under investigation, but no doubt the researches in the industrial laboratory will lead to a method by which they can be produced commercially. The importance of being able to obtain sheets direct without rolling will be appreciated. The iron is of first-class quality, capable of undergoing very considerable deformations in the cold. Tests on tubes and plates have been made in the draw bench, and it is surprising with what facility the metal can be worked. The material is therefore highly suitable for purposes of stamping, both in the form of plain annealed plates (black plates) or of tinned plate. Finally, on account of their purity, these sheets are especially adaptable for use in the construction of electric machinery. Dr. Max Breslauer of Berlin has demonstrated the important aspect of this question, both from the point of view of magnetic properties and of regularity of thickness and compressive strength. The efficiency of alternating motors and transformers, and also of direct current motors, is increased by using this material in their construction. He concludes that the use of electrolytic iron constitutes a real progress, both as regards hysteresis and permeability. In transformers the saving in weight of material is 33 to 40 per cent. The capacity of alternating motors can be increased by 30 per cent, running at the same temperature, and occupying the same space. In direct current machines, 16 per cent of the iron can be saved.

As a Raw Material for Fusion.—Without doubt electrolytic iron will be able to compete successfully with Swedish iron. The quality is much more regular, and the crude metal, being very brittle, can easily be broken into pieces of any required size, however small, and, at the same time, it can be supplied in suitable thicknesses. The cementation of such products would be more regular than those ordinarily used. Tests made at various steel works have shown that tools and special steels manufactured from this material give results at least equal to those obtained with Swedish iron. The cost price is the only remaining consideration.

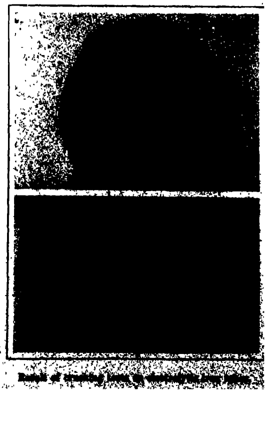
COST OF MANUFACTURE.

The principal factors which make up the cost price are the electric energy and the pig iron. It has already been mentioned that 2 tons of extremely pure iron can be produced per kilowatt-year. Using a current of 800 amperes per square meter, instead of 1,000 amperes, the voltage drops to about one half, and the production per kilowatt-year is nearly doubled. Working with a still lower density, the yield can be even further increased. In countries where the cost of motive power is high, it would pay to work at 500 amperes or even less. It would then be possible to produce 3 to 4 tons, and even more, per kilowatt-year. If the cost of the unit be taken at 1 centime (0.1d.), an ordinary figure in the Alps, and using a current density of 1,000 amperes, the cost of current would not exceed 43 francs per ton of iron produced. Since pig iron is used as the raw material, it may be reckoned that there is about 10 per cent of waste in the form of sludge, graphite, etc. The price of the pig iron would vary according to the locality, and in the mountainous country it would run at about 64 to 88 shillings per ton. The price, however, would be higher in those localities where the electric current was cheapest, and *vice versa*. The average outlay on pig iron per ton of electrolytic iron would therefore be from about 72 to 80 shillings. To this would still have to be added the cost of labor, maintenance, cost of electrolyte, depreciation, and interest on the capital cost of the plant. These various amounts have not yet been definitely ascertained, but the total cost price, based on current prices for material and labor, of the electrolytic iron, in the condition in which it leaves the electrolyte bath, would probably not exceed £6 to £7 12s. per ton, according to the locality.

COMMENTS BY SHERARD COWPER-COLES.

The secretary of the Iron and Steel Institute makes public the following as the substance of a communication sent to him by Sherard Cowper-Coles of Sunbury-on-Thames, England, in which exceptions are taken to some statement in Prof. Guillet's paper:

Mr. Sherard Cowper-Coles wrote that he considered



Result of crushing [illegible]

* From a paper prepared for the abandoned fall meeting of the Iron and Steel Institute at Paris. The author is professor of metallurgy at the Conservatoire National des Arts et Métiers, Paris. Reproduced by courtesy of *The Iron Age*.

the paper by Mr Guillet very misleading in some of its statements. In 1908 he (Mr Cowper Coles) read a paper before the Iron and Steel Institute entitled "The Production of Finished Iron Sheets and Tubes in One Operation," describing in considerable detail his electrolytic process for the direct production of iron tubes, cylinders, and sheets. In that process a mandrel revolving at a critical speed, so as to give sufficient skin friction between the electrolyte and deposited metal was employed to obtain a close homogeneous deposit and at the same time enable a high current density to be employed, the solution being kept neutral by bringing it in contact with iron oxide as described in Mr Guillet's paper. In the following year Mr Boucher approached him (Mr Cowper-Coles) regarding the process and asked if he would grant him a license to work it in France and Switzerland. This was done and a small trial plant was thereupon set up in Switzerland and Mr Boucher produced a number of tubes. A company was ultimately formed called Le Fer to acquire the license that had been granted to Mr Boucher.

Mr Cowper-Coles's object in setting out these facts is to show that all the preliminary work was carried out in Great Britain at great expense and much labor. That that was so could hardly be gathered from what he thought was a somewhat ungenerous statement which constituted the only reference to the process in Mr Guillet's paper.

In 1907 Mr Cowper-Coles took out a patent involving the use of a 20 per cent solution of sulphocresylate of iron and endeavored to manufacture weldless tubes, using a rotating cylindrical mandrel. This process which was analogous to the Elmore process for making copper tubes has not yielded results of much importance.'

The Cowper-Coles process he continued is in no way analogous to the Elmore copper process which consists in using an agate burnisher. He thought it should be known that the process described in Mr Guillet's paper had been worked out in England and that works are to be erected in the Midlands to carry out the process on a commercial scale. He (Mr Cowper-Coles) had all the necessary documents for proving the statements he had given.

Business Aspect of the Kelp Proposition*

By Frederic P Dewey

It is thoroughly well established that the giant kelps of the Pacific provide an enormous store of KCl. Various papers have appeared upon the broad general aspect of the question but for the most part they have dealt in glittering generalities and many of them have started in the middle of the proposition. Many writers neglect or slur over the gathering and preliminary drying of the kelp and base their real consideration of the subject upon the air-dried material. This is very attractive and easy to do but the cost of the air-dried kelp is a most serious business consideration.

There are various technical and business problems connected with the matter. Without in the least doubting the eventual solution of these problems it may be said with entire safety that their solution with financial profit will require the expenditure of much time and money under the best technical and business direction and that it must be several years before KCl from kelp can become a commercial commodity if it ever does.

The consideration of the subject divides itself naturally under the following heads

Harvesting the kelp.
Air-drying
Oven-drying
Distillation.
Crystallising KCl
Marketing.

To start with the growing kelp. How can it be harvested?

It will be an entirely new industry and manifestly various machines of different types will have to be constructed and subjected to actual practical tests before an efficient and economical machine is secured. Dr Cameron has suggested 1 000,000 tons of KCl as a conservative annual yield. This would mean the harvesting of approximately 30,000,000 tons of kelp. This harvesting cannot extend over the whole year. Just how long it may last cannot yet be definitely known, but in any event the vast machinery required to harvest 30,000,000 tons in a short season must stand idle a good part of the year at a heavy interest charge against the product.

Having brought the kelp to shore it must be dried. To produce a ton of KCl, approximately 27 tons of water must be evaporated. Clearly the most inexpensive natural means for drying must be adopted, but even this would require the construction of drying sheds

* From the Journal of Industrial and Engineering Chemistry

covering an enormous area and the building of especially designed machinery to distribute the wet kelp on the drying shelves and to gather up the dried stuff. As with the harvesting machinery these sheds and machinery must remain unemployed a good part of the year.

There is however a limit to the extent that natural drying in open sheds can be carried. When about 25 tons of our 27 tons of water have been evaporated provision must be made to protect the efflorescing KCl which will soon be produced on further drying. This will require the application of artificial heat. It may possibly be assumed that this can be obtained from the kelp itself in a subsequent operation. By proper oven drying it is possible to recover 40-50 per cent of the KCl as efflorescent salt by simply shaking it off from the dried kelp.

The recovery of the balance of the KCl from the dried and shaken kelp requires the breaking up of the organic matter of the kelp body and this must be done with as full as possible utilisation of its value. Simple burning with the utilisation of its heat value only will not be sufficient, even if we now had a furnace adapted to avoid inclosing unburned material in the inorganic salts by sintering and to avoid undue loss of KCl by volatilisation.

At present there does not seem to be any method available for this part of the work except destructive distillation with the recovery of the condensable by products and the utilisation of the gas first to heat the retorts and secondly for the oven drying of the kelp as far as may be. Probably there are no technical difficulties in this operation but it must be remembered that only about half of the weight including the effloresced KCl of the oven dried kelp is organic matter. In other words broadly speaking in the production of one ton of KCl only one ton of organic matter is available for the production of by products of distillation. On the other hand the total production of such by products in the recovery of 1 000 000 tons of KCl would be so large that much of them would have to be transported long distances to find a market and therefore the profit of the operation would largely depend upon freight conditions.

Undoubtedly a limited amount of the residue from the retorts could find direct application as a fertiliser within a certain radius but the real market for KCl is on the Atlantic coast and under the present freight conditions of 80 cents per 100 pounds the KCl must be dissolved and recrystallized. Upon the opening of the Panama Canal and the expected halving of the freight rates the distillation residue might possibly better be shipped direct.

The mother liquors from the recrystallising of the KCl will contain iodine and when sufficiently enriched they may be treated for the recovery of this element.

It would be a liberal estimate to assume that the by products recovered including the iodine would have a value sufficient to pay for all of the operations upon the air-dried kelp. If we do this and also assume that after sufficient trial and development of the necessary machinery the kelp can be harvested for 25 cents per ton and air dried for 15 cents per ton more a ton of KCl laid down on the Atlantic coast would cost $28 as follows

Harvesting 30 tons at 25 cents	$7 50
Air drying 30 tons at 15 cents	4 50
Freight 1 ton at 80 cents per 100 pounds	16 00
	$28 00

On the completion of the Panama Canal it is expected that the freight will come down to $8 per ton but the present prices of KCl must be very profitable to the German Potash Syndicate and if actually faced with the possible loss of its American trade the prices would undoubtedly be reduced. This reduction might even wipe out the advantage of the low water freight.

In conclusion it would appear that the feldspars have not yet been displaced by the kelps as a possible source of potash.

Parsons Marine Turbines

The total horse-power of marine turbines of the Parsons type completed and under construction in England and elsewhere amounts to about 12 360 000 horse-power an increase during the last 12 months of about 1 760 000 horse-power, according to a statement in the *London Times*. Of the total nearly 10 520 000 horse-power is or will be, employed for the propulsion of warships and over 1 800 000 horse-power in mercantile vessels and yachts. The use of geared turbine machinery for ship propulsion is extending rapidly and 136 vessels built or building are wholly or partly fitted with such machinery of an aggregate of about 1 000 000 horse-power. These include 68 vessels of 620 000 horse-power ordered during the past year by the Cunard White Star Canadian Pacific Railway, Union of New Zealand, Ellerman, and other lines.

New Hydrogen X-Ray Tube

By H Clyde Snook

Following extended research work in the Snook Roentgen laboratories at Philadelphia Pa comes the announcement of the development of a new type of X ray tube known as the hydrogen tube. Results from its use in a number of disinterested Roentgen ological laboratories over a period of several months would seem to indicate that the new type of tube possesses important points of superiority over other X ray tubes in use at the present time.

One of the most frequent and annoying defects in X ray tube construction in the past has been the difficulty encountered in adjusting the vacuum to a satisfactory working condition. The most striking characteristic of the new hydrogen X ray tube is found in the fact that it can be regulated either up or down as to vacuum both accurately and quickly.

The Snook Kelly hydrogen X ray tube.

The vacuum is lowered by means of the osmosis of chemically pure hydrogen through a metallic tube closed at one end which acts as an osmotic membrane when heated to redness. This metal tube is sealed into the main wall of the vacuum chamber its open end communicating with the vacuum. Its closed end protrudes into a body of hydrogen contained within a small glass chamber attached to the bulb proper. The metal tube is heated to redness by passing the current across a short spark gap.

To raise the vacuum a similar tube within the raising attachment is heated to redness by the same means. Although under normal working conditions the hydrogen pressure within the vacuum (so called) is but 0001 to 000001 millimeter of mercury absolute pressure it behaves according to the well known principle that gases are like vacuums to each other. Atmospheric air is excluded from the vacuum by the metallic tube—yet when the tube is heated as described above, hydrogen is discharged osmotically into the atmosphere by its own pressure. Hydrogen in minute quantities, therefore actually passes outward from the vacuum when the raising attachment is in operation. The vacuum of the tube is thereby raised in accordance with the length of time the operation is continued.

Roentgenologists report that the hydrogen tube displays marked stability and disinclination toward heating, due presumably to the fact that hydrogen possesses the lowest atomic weight of all known gases and displays little chemical avidity for most metallic substances. Extraordinary penetration has also been noted, comparative radiograms showing one Benoist number higher than with any other type of tube.

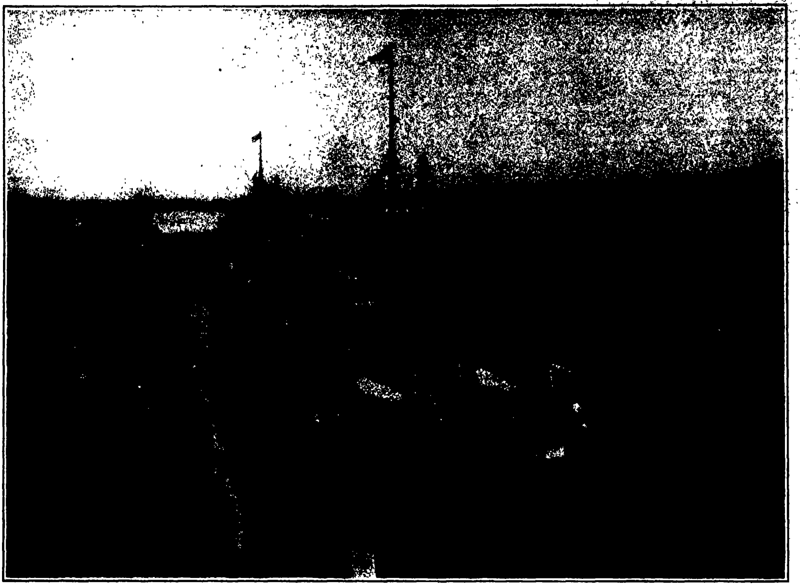
Greater efficiency more uniform result and longer life appear therefore to be the advantages of the hydrogen tube as demonstrated to date.

Simultaneously there has been evolved, in the same laboratories an air-cooled type of hydrogen tube with its vacuum subject to regulation by the same means as the standard type referred to above. By the use of the air cooled hydrogen tube long fluoroscopic work may be punctuated by making radiograms and administering X ray therapy in massive doses as frequently as the operator may desire.

The hydrogen tube is the result of joint work by Mr H Clyde Snook and Mr Edwin W Kelly.

Electro-chemical Generators

The Neuhausen Aluminium Works recently ordered three electric generators for an increase in their large plant at Chippis in the Swiss region. These machines are built by the well known Oerlikon Works and are to be ranked among the largest yet to be constructed for electro-chemical use being of 2 650 kilowatt size or 3 850 horse power. Such machines deliver as much as 8 000 amperes at a tension of 340 volts, and the standard speed is 300 revolutions per minute. The generator in each case is direct coupled to a hydraulic turbine, and it is built to stand an overload up as high as 3,000 kilowatts while if necessary the speed can be increased to nearly twice the standard or to 540 revolutions per minute. As far as we know the present machines appear to be not only the first to be built, at least in Europe for such a large output and as heavy a current with a relatively high speed but appear even to be the largest generators yet to be built on this side for electro-chemical purposes.



Vessel in the upper Gatun lock as seen from the balcony of the control house.

Electric Towing in the Panama Canal Locks

Ingenious System and Novel Electric Locomotives

INVESTIGATIONS of collisions between ships and lock gates invariably show that "there was a misunderstanding in signals between the captain and engineer." Bearing in mind that the engineer of a ship is so situated that he does not know the exact position of the ship, with respect to the lock, he cannot check his actions by the probable result. A system, therefore, which permits checking the movement of the ship with the signal given by the pilot or captain of the ship, will eliminate improper manipulations to a very great extent.

Various systems are in vogue at drydocks, which are based on the principle that the operator sees the result of his action. The employment of winches, or capstans, has been looked upon with a great deal of favor. These are usually placed at intervals along the dock walls, and the lines from the ship are carried forward to the successive capstans as the ship advances. Such a system involves the risk of the ship not being properly safeguarded when the lines are transferred to successive capstans. An improvement has been made by the installation of a capstan at the head of the dock, centrally located, and used for imparting a straight motion to the ship. Numerous lines from the ship to the dock wall are carried by men; and the capstans are employed to counteract any wind pressure, currents, etc., and assist generally in maneuvering the ship. While an improvement over former methods, it did not, however, possess the flexibility and reliability required for the operation of the locks of the Panama Canal. Neither would it have eliminated the breaking of the lines at critical moments, which is regarded as one of the essential requirements in successfully handling ships in canal locks.

After a very thorough study of the entire problem of maneuvering ships through the locks of the canal, it became evident that they should not proceed through the locks under their own power, and that a substitute for the ship's power should embrace the following requirements:

(a) Ability to place the ship in proper relation to the lock.

(b) Capability of keeping the ship to its course.

(c) Accelerating and retarding the ship without rupturing the lines.

(d) The lines when once attached should be used without change for lockage in flight.

(e) A small number of skilled operators rather than a large number of unskilled men to co-ordinate.

The towing system described in the following pages was designed and patented by Mr. Edward Schildhauer,

Method of attaching the electric locomotives to a vessel for towing through a lock.

electrical and mechanical engineer of the Isthmian Canal Commission; and the forty towing locomotives and all the electrical apparatus for operating the locks, were built by the General Electric Company.

TOWING SYSTEM.

In passing through the canal from the Atlantic to the Pacific, a vessel will enter the approach channel in Limon Bay, which extends to Gatun, a distance of about 7 miles. At Gatun it will enter a series of three locks in flight and be raised 85 feet to the level of Gatun Lake. It may then steam at full speed through the channel in this lake, for a distance of 24 miles, to Bas Obispo, where it will enter the Culebra Cut. It will pass through this cut, which has a length of nine miles, and reach Pedro Miguel, where it will enter a lock and be lowered 30 feet. Then it will pass through Miraflores Lake for a distance of 1½ miles, until it reaches Miraflores, where it will be lowered 55 feet through two locks, to the sea level, after which it passes out into the Pacific through an 8½-mile channel.

The main features of all the lock sites are identical; and the following brief description of the Gatun Locks, with special reference to the arrangement of the towing tracks, ship channels, inclines, and approaches, gives a conception of the towing scheme.

There are two ship channels, one for traffic in each direction, which are separated by a center wall, the total length of which is 6,330 feet. There are two systems of tracks, one for towing and the other for the return of the locomotive when returning idle. This, however, refers only to the outer walls. For the center wall there is only one return track in common for both the towing tracks. The towing tracks are naturally placed next to the channel side, and the system of towing requires normally not less than four locomotives running along the lock walls. Two of them are opposite each other in advance of the vessel, and two run opposite each other following the vessel, as seen in line cut on this page. The number of locomotives is increased when the tonnage of the ship demands it.

Cables extend from the forward locomotives and connect with the port and starboard sides, respectively, of the vessel near the bow, and other cables connect the rear locomotives with the port and starboard quarters of the vessel. The lengths of the various cables are adjusted by a special winding drum on the locomotive to place the vessel substantially in mid-channel. When the leading locomotives are started, they will tow the vessel; while the trailing locomotives will follow and keep all the cables taut. By changing the lengths of the rear cables, the vessel can be guided; and to stop the vessel, all the locomotives are slowed down and stopped, thus bringing the rear locomotives in action to retard the ship. Therefore, the vessel is always under complete control quite independent of its own power, and the danger of injury to the lock walls and gates is very greatly lessened.

The illustrations show how effectively the four locomotives keep the vessel under control and in the center of the channel, and give a general idea of the method of handling vessels. They also show general views of the lock walls, towing tracks and the inclines, the steepness of the latter being especially noticeable.

The towing [illegible]

extending the entire length of the track and located centrally with respect to the running rails. It is through this rack rail that the locomotive exerts the traction necessary for propelling large ships and climbing the steep inclines.

A rack rail is also provided on short portions of the return track so as to lower the locomotives safely from one level to the next. The steepest slope is 23 degrees, or 44 per cent, hence the need will be seen for rack rail even on the return track, it being noted that any traction locomotive with the usual wheel drive, even with the brakes set, would begin to slide on a 10 per cent grade, and, therefore, could not be controlled. With a rack rail, however, traction is limited only by the capacity of the driving motors and not by the adhesion of the wheel treads on the rails.

The rack rail is of the shrouded type, and each tooth space has a drain hole cast in the bottom so as to carry off water and other accumulations to suitable drain pipes or ducts set in the concrete of the walls. A further feature of the rack rail is the projecting edges, which permit thrust wheels attached to the locomotive to run along the under side and prevent overturning of the locomotive, in case some unforeseen operating condition should produce an excessive pull on the towline. These thrust wheels serve to counteract the lateral component of the towline pull and the flanges act for emergency only, as the weight of the locomotive is, however, sufficient to prevent overturning with a normal pull of 25,000 pounds on the towline.

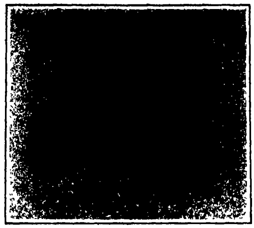
Three-phase, 25-cycle, 220-volt alternating current is used for operating the locomotives, and the current is supplied to the locomotives through an underground contact system. Two T-rails form two legs of the three-phase circuit and the third leg is formed by the main track rails. A specially designed contact plow slides between the two "T" conductors and transmits the power from the rails to the locomotive. This contact plow also passes through the slot opening in the conduit cover and is flexibly connected to the locomotive in such a manner as to follow all irregularities in the tracks and crossovers, and, therefore, insures a continuous supply of power.

LOCOMOTIVE DESIGN.

The working parts of the locomotive are supported by two longitudinal upright side frames of cast steel, connected by transverse beams. These frames are in effect deep rigid trusses, having upper and lower members connected by posts and diagonal braces. The pedestals for the wheel axles are of the usual locomotive type. Springs are interposed between the tops of the journal boxes and the tops of the pedestals, and the locomotive is thus mounted upon four wheels, the wheelbase being 12 feet, and the overall length of the locomotive over 32 feet.

Each axle is driven by its own independent motor; and, as the construction is identical at both ends of the machine, a description of one will suffice for both.

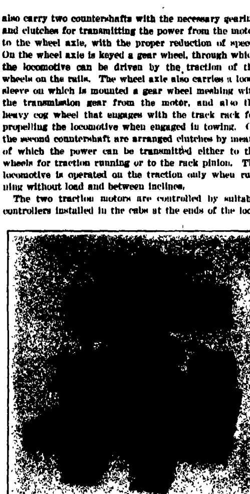
The motor is of the three-phase, slip-ring type, inclosed and identical to the rugged steel mill design. The motor is carried on a pair of cast steel suspension brackets, which are journaled on the wheel axle at one end, and located just inside the wheel on either end of the axle. The other ends of these brackets are connected by yielding supports to one of the cross members of the main frame of the locomotive. These brackets



Traction motor unit of one of the Panama electric locomotives.

also carry two countershafts with the necessary gearing and clutches for transmitting the power from the motor to the wheel axle, with the proper reduction of speed. On the wheel axle is keyed a gear wheel, through which the locomotive can be driven by the traction of the wheels on the rails. The wheel axle also carries a loose sleeve on which is mounted a gear wheel meshing with the transmission gear from the motor, and also the heavy cog wheel that engages with the track rack for propelling the locomotive when engaged in towing. On the second countershaft are arranged clutches by means of which the power can be transmitted either to the wheels for traction running or to the rack pinion. The locomotive is operated on the traction only when running without load and between inclines.

The two traction motors are controlled by suitable controllers installed in the cabs at the ends of the locomotives; and the circuits are such that both motors can be controlled from either cab, and can be operated singly or in multiple as desired.



Mechanism of the windlas that handles the towing cable.

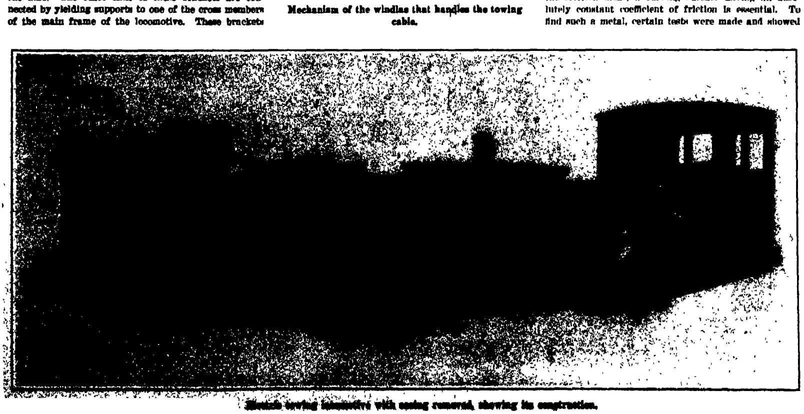
In connection with each motor a powerful brake is installed; and, as during operation the motors are at all times geared either to the axles or to the cog wheels, the truck wheels are not provided with any brake rigging.

These brakes are operated by a solenoid, the winding of which is in circuit with the controller of the motors, so that when the current is turned on to energize the motor windings, the solenoid will lift its core and thereby release the brakes. The first point of the controller raises the brakes without applying power to the motors, thereby providing a coasting point. But should the motor current be shut off, either intentionally or accidentally, the core will instantly drop by gravity and its weight will exert a powerful leverage upon the brake levers to stop the motor and the locomotive. This action occurs simultaneously on both motors, and brake action is powerful enough to stop the locomotive within two revolutions of the wheels.

In addition to this automatic brake, means are provided for applying the brakes manually in order to supplement the action of the automatic feature, if necessary, when descending a grade or where approaching a rack rail.

Passing now to the features which render the locomotive peculiarly adapted for towing purposes, it is observed that there is a large horizontal drum mounted above the body of the locomotive at its middle length, which handles the towing cable that is wound upon it. This drum is carried on a heavy tubular column that is fixed in a substantial pedestal built into the main frame of the locomotive. Below the drum, and mounted on the same column, is a large internally geared wheel, which is connected to the drum by a slip friction clutch, consisting of a steel disk held between two alloy rings with a yielding pressure produced by a series of coiled springs. Two separate electric motors are provided for operating this towing drum, one driving through bevel and spur gearing to the large internally geared wheel, which is for fast coiling in or paying out the cable. The other motor drives through a worm gear, and thence by a spur gear onto the same internally geared wheel, clutched with the towing drum, and is used for taking in slack of the cable, and controlling vessels when towing. The fast running gear is always connected, but the slow working power gear is connected by means of a clutch, which is thrown out automatically by a solenoid that is energized by the movement of the controller governing the fast winding motor. The first point of the controller energizes the solenoid, and frees the clutch of the power gear, and the second point starts the coiling motor.

One of the most important parts of the locomotive is the "slip-friction" device consisting of the two special alloy rings, and the steel disk fastened to the rope drum, the amount of tension on the tow line being adjusted by the pressure between these three disks, which is obtained by tightening the spiral springs on the clamping ring. In order, therefore, to make the slipping tension of the towline proportional to the pressure between the friction disks, a rubbing surface having an absolutely constant coefficient of friction is essential. To find such a metal, certain tests were made and showed



Electric towing locomotive with casing removed, showing its construction.

that the low friction metal, having a friction coefficient of 0.1, is practically constant under all pressures and condition of the surfaces, and, therefore, was selected for the work. This metal also showed but very little difference in coefficient between starting and running. The results of the special tests were furthermore amply verified by the final test of the friction disks of each machine under full rated towline pull of 25,000 pounds. All forty machines were given this slip test twenty-five times from each cab, and all passed the Government requirement not to exceed a variation of 5 per cent above or below the normal of 25,000 pounds.

In connection with the slip test, further data on the slow winding motor was obtained. The winding motor is a 20 horse-power (one-hour rating), three-phase, high torque, squirrel cage type, induction motor controlled from a drum type reversible controller in either of the two cabs. And it has ample power to take care of any sudden pull on the towline up to 40,000 pounds, which is well above the normal requirement of 25,000 pounds. The speed of winding is at the average rate of 12 feet per minute.

The rapid-coiling motor is permanently geared to the drum, and is of the same type, size and capacity as the winding motor. It is subjected to its maximum load when accelerating the heavy drum to the high speed required for coiling or paying out the rope, this being sixteen times the slow winding speed at full load, or about 200 feet per minute.

The slow-winding and the rapid-coiling motors are operated by similar controllers and the circuits electrically interlocked so as to prohibit application of power to either motor unless the controller of the other motor is in the "off" position.

Each of the two main traction motors has a rating of 75 horse-power, and is of the slip ring induction type, operated by a system of contactors with master controller in each cab. The motors, by means of the change in gearing from straight traction to rack rail towing previously described, drive the locomotive at a speed of 2 miles per hour when towing and 5 miles per hour when returning idle. These motors act as induction generators running above synchronous speed when the locomotive is passing down the steep inclines and thereby exert a retarding brake effect to keep the speed uniform.

Space does not permit of a detailed description of the locomotive control apparatus, but a fairly good idea will be had by reference to one of the illustrations.

SUMMARY.

The towing locomotives, as described and illustrated, possess the following operating characteristics:

1. While towing, the speed can be regular from zero miles to two miles per hour.

2. While running idle, the speed can be regulated from zero to five miles per hour, permitting return trips at increased speed.

3. The windlass will pay out or wind in cable at the low rope speed and at the full tow line pull of 25,000 pounds, either when the locomotive is running or at rest.

4. The windlass will pay out or coil in cable at the high rope speed with the tow line taut, either when the locomotive is running or at rest.

5. The windlass is equipped with a safety friction device, which is adjustable to any predetermined value of the tow line pull.

The first impression may be gathered that these machines are somewhat complicated; but, considering their many functions and the great flexibility for performing them, the design is in reality peculiarly simple. The locomotives have fully demonstrated in actual operation that the requirements contemplated by the Isthmian Canal Commission have been successfully met.

The locomotives have a net weight of 86,800 pounds and a gross shipping weight of 92,500 pounds.

During the first three months of commercial operation of the canal, from August 15 to November 15, the cargo transported through the canal and towed through the locks by the locomotives amounted to 1,079,521 tons. During the fiscal year ending June 30, 1914, the Panama railroad carried 648,178 tons of through freight between the two seaboards, and in the preceding fiscal year 594,040 tons. From this it is seen that between six and seven times as much cargo is passing over the Isthmus now as passed over this route when goods were trans-shipped by rail.

The Hygienic Home

Some Facts About Ventilation and Fresh Air

By Dr. John B. Todd

The home is the foundation of all society; its organization is the objective realization of the wisdom and culture of its founders. The ideal home is that in which, with the means available, there is an adjustment of environment that will result in health, comfort and future development of all members of the family. In the establishment of an ideal home it is not so much what one does, or does not do, but rather whether in a given environment and within one's means one does really those things that count for health and comfort.

One of the primal conditions necessary for an ideal home is the perfect health of all its members. The first wealth is health, for while there are exceptional cases where an indomitable will is able to overcome the handicap of ill-health—as in the case of the illustrious Darwin—still, with perfect health much more could be accomplished. Of the conditions in a home that are factors in producing ill health and disease, the matter of ventilation is very important. Probably poor ventilation in houses, schools, churches and all other indoor places where people spend more or less of their time, is the cause of more deaths and more ill-health than all of the wars. The effect of living in ill-ventilated rooms is very insidious and slow to be noticed, but it is none the less fatal in its results. Sanitarians have made many experiments trying to find out just what it is in bad air that is bad, but their results so far have been unavailing. Their methods are too clumsy. According to their beliefs carbon dioxide—the product of respiration—is not harmful. The foul smelling odors that we notice in close rooms produce no ill effects, rebreathing air is not unsanitary, that the bacteria we take in through the air is of a negligible quantity, that the breathing of dusty air is not bad unless in some trades, as grinders of metals, pottery, etc.

The fallacy is in trying to find bad air by considering and excluding the constitutents one by one. In the same way there is no such thing as a wagon, for when we inquire:

Is the pole the wagon?
No.
Is the box the wagon?
No.
Is the seat the wagon?
No.
Is the wheel the wagon?
No.
Is the axle the wagon?
No

we fail to find the wagon; but when one is knocked down and run over by a wagon, there is no question of its existence. Thus when we consider the diseased conditions that exist among people who habitually breathe bad air, there is no doubt of its reality. First, we find a slow but steady lowering of resistance, the color of the skin is pale and not of the clear, ruddy tinge of people living out of doors, there is sub-oxidation, the stale indoor oxygen has lost its vitality, and in consequence they become easily fatigued. Then anaemia follows as the precursor to a host of diseases; bronchitis, tuberculosis, laryngitis, rheumatism, and diseases of the digestive system. Price examined 1,413 workers in cellar bakeries and the best tailor shops, and found over two-thirds diseased.

From all these facts it becomes very evident that we need fresh indoor air—air that has had its oxygen made active by the actinic rays of the sun and the buffeting of storms and winds. In the ideal home the problem is, first, to build in a manner that our houses are cold-proof, and therefore it becomes a matter of better architecture. From 25 to 50 per cent of the fuel we burn is wasted to balance the heat loss from our windows, walls and floors. If the heating problem were only to warm the air in our homes, the cost of fuel would be insignificant.

We want windows in great plenty, for light is as necessary as air for healthful rooms, but the heat loss from the windows in enormous. A room inclosed by glass but with no heat is as cold as the outside, and added to the coldness is the stale, dead air with its inactive oxygen. This is the reason of the failure of glass-inclosed sleeping-porches. Air of itself is a nonconductor of heat and we have only to build our homes with two or three air spaces in the walls to make them practically cold proof. Of course all windows, except those having fresh air screens, should have perfect fitting storm sash, and the floors should have a nonconductor filling between the joists. The extra expense of this construction would be returned a hundred fold in health, comfort and money saved. Then, no matter what heating and ventilating system you have, there should be several windows fitted with fresh air screens.[1] These are wood frames made to fit closely the window frame opposite the lower sash in such a manner that all openings for drafts are closed. This frame is covered with a medium quality of unbleached cotton cloth. The lower window is left free and can be raised and lowered as occasion may require. When the window is raised the screen acts as a permeable membrane and allows the fresh air to slowly diffuse into the room and permits no draughts. There is not a day during the cold months of the year when these fresh air screens cannot be used at longer or shorter intervals; and another great benefit from their use is that the air is filtered and dust-free. Dusty air is one of the factors that causes disease and we have greatly under-estimated the evil effects of breathing dust laden air.

There is one part of the home in which we spend one-third or more of our lives, which should receive our earnest consideration to render it sanitary in every respect, and that is the sleeping room. If there is any part of the 24 hours in which we want to be comfortable, it is when we retire to woo sweet sleep, and there is also no part of our time when we really need fresh air and live oxygen as much as we do here, that we may arise refreshed and vigorous. Too often we have not been able to reconcile the idea of comfort and fresh air, and we have taken comfort and let the fresh air go.

However, it is possible and perfectly practical to sleep in comfort during the winter and at the same time have our sleeping room filled with sweet, fresh air. We have only to place a properly constructed fresh air screen opposite the lower sash in one or two windows, then with the windows raised at night we can sleep in perfect safety with the room filled with fresh, invigorating air, and one will arise in the morning with renewed energy. There will be no draughts; rain or snow cannot come in, and the room will not seem cold. Some mothers will claim that this is best for adults, but that it will not do for small children, as they will get uncovered and take cold. Many of these same mothers have learned that it is beneficial for the baby to sleep out of doors in the baby carriage during the day, even through the coldest weather, when the child will sleep quietly and never disarrange the clothing. A little thought reveals the fact that children kick off the clothing nights because they are uncomfortably warm in the heated, close, stuffy sleeping rooms, and that children sleeping under these conditions are habitually getting cold. What we call colds is a germ infection, and hot, stuffy sleeping rooms furnish favorable conditions for its development, while sleeping in cool, fresh air develops the greatest possible resistance to the infection. Mothers should use their reason to fortify their courage, and provide fresh air screens for the children's sleeping rooms. They will not kick off the bedding, but instead will cuddle down and sleep quietly. Their resistance to colds and infections will be increased and they will make more vigorous growth.

If there is any occasion in our lives when we require fresh air more than another it is when we are confined to our bed by reason of illness. It is at this time that the use of fresh air screens gives the greatest comfort and furnishes the greatest aid to recovery. Stubborn, desperate cases of anaemia have much greater chance to mend as soon as continuous fresh air conditions are provided. In pneumonia it is well known that the comfort and condition of the patient are improved under fresh air conditions, and the chances of recovery greatly increased.

We all have learned by personal experience to appreciate the comfort and benefit of fresh air living. We may read and have our reason convinced, our friends may talk fresh air until we have not an objection to propose, still, until our knowledge comes from personal experience, it is of no value to us in our lives. You should acquire that personal experience by having at least one window in your sleeping room fitted with a properly made fresh air screen, for you will quickly perceive the benefit derived, and see the want of more screens. When actual knowledge is acquired in this manner, those who can do so will be satisfied with nothing less than an outside screened sleeping room, which is the greatest convenience, luxury and necessity of an ideal home. All the bed dust is excluded from the home, and the actual housework is very much lessened. The temperature in a sleeping porch during cold weather will be from 12 to 20 deg. Fahr. warmer than the outside. When the outside temperature reaches 45 or 50 degrees, a person will not feel comfortable without an outside door open.

The universal living in fresh air conditions would do more to [illegible]

Arithmetical Machines—II*

Their History, Theory and Methods of Construction

By H. E. Goldberg, M. W. S. E.

Concluded from SCIENTIFIC AMERICAN SUPPLEMENT No. 2038, Page 60, January 23, 1915

Key-set Machines.—In the class of key-set adding machines are to be found some of the best known machines, such as the Burroughs and Wales. The Burroughs is constructed about as follows: (Figs. 7 and 8.)

There is a bank of keys for each decimal place. Each bank is provided with keys having the values 1, 2, 3, 4, 5, 6, 7, 8, and 9. Co-operating with the keys of each bank is a bar *A*, which has a series of projections upon it, P^1, P^2, P^3, up to P^9. Notice that P^1 is very close to the bottom of the key 1, in fact, just one step removed. P^2 is two steps from the bottom of the key 2; P^9 is nine steps from the bottom of key 9. There is a spring *C* tending to move the gear bar to the left, but it is prevented from so moving by the interference of the cross bar *D*. When the operator depresses a key, he pushes its bottom into the way of the co-operating projection upon the bar. The operator, having thus set up the keys for the number desired, pulls the handle. This advances the bar *D* to the left, thus removing its interference. The bars *A* follow the bar as far as they can, that is, until each bar hits the projection upon the key depressed in its bank Each bar is thus advanced a number of steps corresponding to the value of the key depressed. Some of you have already noticed the fact that if no key is depressed there is nothing to stop the gear bar in its advance. It, therefore, would move the maximum amount, say nine Of course, this must be prevented in an actual machine, and is so prevented by a special stop which prevents the bar *A* from moving, but which stop is pushed out of the way by the pushing down of any key

Totalizer.—You will notice that Fig 8 is drawn to a larger scale than Fig. 7. This is for the purpose of illustrating the totalizer During the advance of the gear bars, the totalizer wheels *T* were not in mesh with them. After the bars have finished moving leftward, the totalizer is lowered into mesh with the bars When the cross-bar *D* is pushed back, it pushes back the gear bars to their original place, and the meshed totalizer wheels are thus rotated an amount corresponding to the value of the keys set up

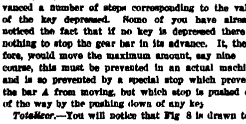

Fig. 8 Fig. 7

Immediately after the rotation of the totalizer wheel by the gear bar, the carrying mechanism operates. The tens-carrying mechanism is constructed somewhat as follows:

Imagine the totalizer wheels *T* mounted on an axle and each wheel provided with a carrying projection *TP*. Between each two wheels is a lever *E* mounted, let us say, friction-tight upon its fulcrum, and having a tooth *F* in the pathway of the pin *TP* The wheel *T* rotates in the direction of the arrow, and in due time its pin *TP* will strike *F* and push away the lever *E* This striking and pushing away of the lever is due notice that the wheel has completed a cycle of motion; that is, arithmetically, it should carry a ten into the next higher wheel to the left. Any wheel that should tens-carry will, therefore, have pushed away its lever. Any wheel that should not tens-carry will not have pushed away its lever. The wheels *T* are rotated by the racks *H* upon the bar *A*, which racks *H* in their turn are pulled by springs *I* fastened both to the racks and to the bar *A*. Each rack *H* is provided with a hook *J* that strikes against the end of the lever *E* whenever that lever is in its approached position; that is, as long as the lever has not been pushed away by the wheel. But when the lever has been pushed away by the wheel, the hook *J* no longer strikes the lever *E*. Instead, it enters below the lever, and thus moves one step further to the right than it would have moved if it had struck the lever.

Notice that each rack *H* is stopped by the lever *E* which is at its right, which lever in turn is moved by the totalizer wheel *T* at its right. That is, finally, the striking of pin *TP* of a wheel against its lever determines that the wheel next to the left shall receive not only the movement which it would otherwise receive, but also an additional step of movement, that is, the tens have been carried into it

The above mechanism is almost identical with that used in the Burroughs and the Dalton machines. Variations are found in the Moon Hopkins and many others The mechanism as described is irreversible, that is,

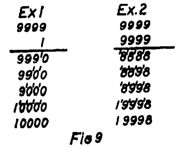

Fig 9

it will not work if the wheels *T* rotate in the opposite direction The wheels would be stuck when the pin *TP* would strike *F* This sticking of the wheel at this point when rotating in the opposite direction is used in the above machines in bringing said wheels to the zero position, as in erasing a number on a totalizer or in the printing of a total The tens-carrying of this mechanism is, of course, successive The wheel to the left does not carry until the wheel to the right has done so, but it is very rapid, and in practice but little time is occupied thereby

A totalizer like the above that accumulates simultaneously, but that carries successively, would digest the examples previously used in the following manner (Fig. 9)

Having already in its stomach the first number, 9999, it swallows the second number as a whole, but does not assimilate it immediately. The result as to the first bite would be ('8), ('8), ('8), ('8). The little (') shows that it is a number temporarily stored up to be afterward carried Mechanically it means that the lever next to the wheel has been pushed away. A series of digestive steps now occur, which successively transform the contents into the number desired. The first digestive step results in the carrying of the units (') into the tens, thus giving ('8), ('8), ('9), 8 That is, the tens rack has moved an extra step. The second digestive step produces ('8), ('9), 98. That is, the hundreds racks has moved an extra step The third step shows ('9), 998. And the last step produces 19998

The totalizers of many machines operate on this principle of delayed seriatim carrying

Any machine whose totalizer would accumulate and carry simultaneously would make but one bite of the whole meal. Thus 9999 and 9999 is 19998. There are no machines on the market whose totalizers operate on that principle, but there are quite a number described among the patents issued in the United States. Let me state here that one mechanical basis for the possibility of accomplishing all the accumulations and all the carryings simultaneously rests on the employment of trains of epicyclic gears.

Ten-key Machines —Let us go a little further into the theory of the ten-key machines. We noted that

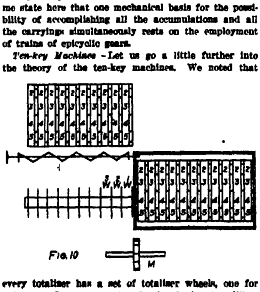

Fig. 10

every totalizer has a set of totalizer wheels, one for units, one for tens, another for hundreds, etc. When on a typewriter a number is printed in a column, as in arranging dollars and cents properly, it is the business of the operator to bring the carriage of the machine to the proper place for the first figure, and from then on they follow in proper order This readily solves the problem for all typewriter attachments such as the Wahl and the Elliott-Fisher On some machines, however, as the Dalton and the Moon-Hopkins, there is no carriage which is first decimally placed by the operator When on such a ten key machine an operator strikes a 1, how does the machine know that it is a 1? Perhaps it is only the first figure of a number, say 127. Historically, the accomplishing of the result was found difficult, as is shown by the fact that in the earlier machines the inventors put down the figures backward Thus 127 used to be put down, first 7, then 2, then 1. The first men to show mechanisms which permitted the figures to be written down highest figure first, units last, were Mr McCaskey and Mr. Helmick, both now of Chicago. The idea occurred to each of them independently, and as they both applied for patents in 1894 some complications arose as to who was the inventor. The means by which they accomplished the result was the introduction of a supplementary carriage capable of storing up a number. (Fig 10)

Let there be a series of windows through which numbers become exposed to the operator of a machine. Let W^1 be the units place window, W^2 the tens place, etc Let *A* be a carriage something like the carriage of a typewriter, and provided in a similar manner with

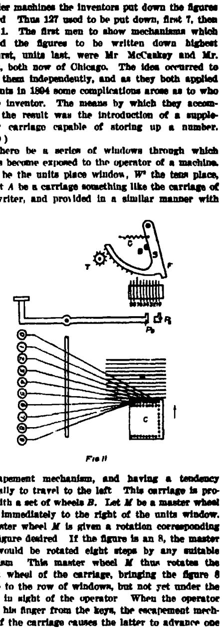

Fig 11

an escapement mechanism, and having a tendency continually to travel to the left This carriage is provided with a set of wheels *B*. Let *M* be a master wheel located immediately to the right of the units window. The master wheel *M* is given a rotation corresponding to the figure desired If the figure is an 8, the master wheel would be rotated eight steps by any suitable mechanism This master wheel *M* thus rotates the leftmost wheel of the carriage, bringing the figure 8 opposite to the row of windows, but not yet under the window in sight of the operator When the operator releases his finger from the keys, the escapement mechanism of the carriage causes the latter to advance one step to the left. The 8, therefore, comes into view in the units window The moving of the carriage has thus brought opposite to the master wheel the next wheel to the right. The pushing down of another key, say 7, by the operator, causes the master wheel *M* to introduce a 7 into this second wheel, and the subsequent escapement and moving of the carriage another step to the left brings this 7 into view in the units window, moving the original 8 into the second window, the whole number now visible being 87 And so on A set of totalizer wheels *T* is located in alignment with the windows, and the carriage with its wheels is, therefore, brought into alignment not only with the windows, but also with the totalizer wheels Further operation depends upon the construction of the machine But in every ten key machine where it is not the operator that first determines what decimal place is to be operated in a traveling carriage is provided for storing up the numbers, which carriage travels toward the left In Fig 10 the traveling carriage is represented as provided with a set of wheels which are rotated by a master wheel.

Fig. 11 represent the construction of the Moon Hop-

---

* A paper read before the Western Society of Engineers and published in the Journal of the Society.

kins and the Dalton machines—more particularly the Dalton. There are ten keys, 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, which are fulcrumed upon an axis. The back ends of the keys are bent together to form a line, and end in a series of projections, P^o, P^1, P^2, etc. Pushing down the finger piece at the front of the key pushes up the corresponding projection upon the back of the key. Traveling immediately above the projections at the backs of the key levers is a carriage C provided with decimal banks of stops, each stop, say, friction-tight in its bearings. The carriage is provided with an escapement mechanism like that of a typewriter. It can thus be seen that when an operator presses, say, key 7, the pin corresponding to 7 will be pushed up as shown in Fig. 11, and the carriage will advance one step to the left, bringing a new bank of stops over the projections that are at the backs of the keys. The keys can then operate upon the next bank of stops, and the number is thus set up upon the carriage.

After the number has been set up upon the stops in the carriage, it is transferred to the totalizer by means of some large sectors S, each of which is provided with a finger F capable of striking the stop opposite to it in the carriage. Normally, the sectors are held back by means of a bar B against the force of the springs G; but when the bar is moved, as is done during the pulling of the handle, its resistance is removed, and the sectors advance as far as they can, that is, until they are stopped by the protruded pins in the carriage. In the Moon-Hopkins machine, racks instead of sectors are used; otherwise the mechanism is about the same. The carrying mechanism in both of these machines, the Moon-Hopkins and the Dalton, is similar in theory to that described in connection with the Burroughs machine.

I have given no space to printing mechanism, which is quite a problem in itself, particularly the non-printing of the zeros at the left of a significant figure. Thus, in a machine which has, say, seven decimal places, the number 1000 would have the three zeros to the right of the 1 printed, whereas there would be no zeros printed at the left of the 1. The printing mechanism varies considerably in the machines on the market. As a general principle, the mechanism for the preventing of the printing of the undesired zeros works by preventing the printing hammers from flying to make an impression.

Multiplying and Dividing Machines.—A multiplying and dividing machine differs from an adding machine in that it must preserve the multiplicand that is set up on the mechanism. All multiplying machines, without exception, preserve the multiplicand during the process of multiplication. In adding machines, the addend is destroyed after the first addition. Figure 12 shows a diagrammatic representation of the mechanism of Grant's arithmetical mill. The machine is supplied with a carriage C capable of being reciprocated by means of a crank D. Mounted in the carriage are a series of racks R, each provided with a handle H, by means of which the operator can advance it in the carriage to any desired position. In the figure, one of the racks only is shown, and it is advanced four steps. Of course, there is a rack for each decimal place, one for units, one for tens, etc. The operator advances each rack the desired amount, and the machine locks these racks into place in the carriage. The rotation of the crank D then advances both carriage and racks toward the totalizer wheels T, which are thus engaged by the racks, and each is rotated an amount dependent upon the distance that its particular rack has previously been advanced. There is, of course, mechanism for preventing the rotation of the wheels T upon the return movement of the carriage and racks, but into that I shall not enter. Notice that by this means the number set up upon the carriage is not disturbed, but can be used over and over.

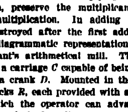

Fig. 12

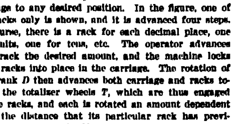

Fig. 13

In Fig. 13 is shown another means that is used in multiplying machines for inserting the number in the totalizer. For each decimal place there is a barrel B, part of which, approximately one-third, is covered with teeth which vary in length from a maximum to a minimum, and have the values 9 to 0. Parallel with the axis of the barrel is a square shaft C, whereon is slidably mounted a gear D, which, by means of a handle H, is slid by the operator opposite any desired point. The rotation of the barrel will, therefore, cause the wheel D to be rotated a number of steps, dependent upon the number of teeth on the barrel B opposite said wheel. That is, it will be rotated only one step when it is opposite the lower end of the long tooth, and nine steps when it is opposite all of the teeth, as at the upper end. The figure to the left shows a development of the surface of the barrel. The reason why the teeth upon the barrel occupy only about one third of the circumference is that the other two thirds is used in the carrying mechanism, which I shall not illustrate at this moment. The above mechanism is the one invented by Leibnitz about 1675 and is now used in the Thomas, the Burkhard, the Tim, the Saxonia, the Archimedes, the Monroe, and many others.

The mechanism in Fig. 14 represents the construc-

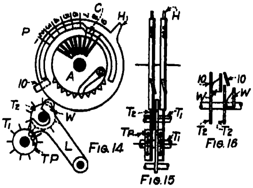

Fig. 14 Fig. 15 Fig. 16

tion of the Brunsviga machine and its brethren, the Thales, the Triumphator, the Marchand, and others. There is a drum A capable of being rotated about its axis, and provided in each decimal place with a mechanism like the one before us. In each decimal place there is a rotatable cam provided with a handle H, by means of which the operator may rotate it about the axis of the drum A. The operator may thus project outside of the circumference of the drum a series of pins P, or retract them into the circumference. In Fig. 14 we see that six pins have been projected, whereas three remain below the surface. Mounted upon axes parallel to that of the drum are two totalizer wheels T^1 and T^2, always in mesh with each other, and each provided with ten teeth. It is evident that a rotation given to the drum about its axis will cause the projected teeth or pins P to pass by the teeth of T^2 and rotate it an amount dependent upon the number of pins set out. Moreover, this will occur at every revolution of the drum.

Should the drum be rotated in the opposite direction, then the wheels T^1 and T^2 will still be rotated an equal amount, but in the opposite direction, thus accomplishing subtraction instead of addition.

The carrying mechanism of the Brunsviga will now be sketched. Upon the wheel T^1 is a pin TP. Co-operating with the pins is a lever L mounted, say, friction-tight upon its fulcrum. It is evident that whenever the pin TP passes by the lever, it will push it away from the wheel T^2 upward toward the drum A. The lever L carries a peculiar wedge-shaped piece W near the drum. Fig. 16 shows a view of the wedge taken on a plane, including the axes of the drum and the two sets of wheels. Mounted on the drum is a special carrying tooth 10. It is normally held to the right by means of a spring, and in passing will not engage the wheel T^2 to the left. In Fig. 16 are shown two adjacent wheels T^2, two wedges W, one to the right and one to the left, and two special carrying teeth 10. The carrying tooth 10 to the right is in its normal position. In passing by the wheel T^2 it would not be interfered with by the wedge W. It would, therefore, miss the wheel T^2. Suppose, however, that previous to the coming around of the carrying tooth 10, the wedge W had been pushed in the way of the tooth 10, as is shown by the wedge to the left: the tooth 10 would now strike the wedge immediately before striking the wheel T^2. It would thus be shoved to the left, and in passing by would engage and turn the wheel T^2 one step. It would thus rotate said wheel a special carrying step.

In order that the carrying steps upon the various wheels of the totalizer shall not interfere with each other, these steps are made successive. One is completed before the other commences. To accomplish this the teeth 10 are placed in a spiral around the drum. The spiral always operates units first, tens next, etc. This may require that there shall be a different spiral for subtraction than for addition, and in the Brunsviga, the Monroe, and other machines this is accomplished by providing two spirals, one of which is effective for addition, and the other one for subtraction.

The above multiplying and dividing machines multiply and divide by repeated addition and subtraction. In multiplying any multiplicand by, say, 7, the multiplicand is rapidly added seven times. Since the highest possible figure is 9 and the lowest is 1, we might say that the average figure is 5, and that these repeated addition multiplying machines require five steps for multiplying by an average figure. There are, however, multiplying machines which do not operate on the repeated-addition principle. They embody in their mechanism a mechanical representation of the multiplication table.

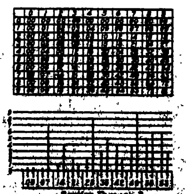
In Fig. 17 is shown the multiplication table as taught to us in school. Please notice that I have filled out each product until it always contains two figures, one in the tens place, another in the units. Immediately below we see a section of this multiplication table taken through 7, and above that are the products represented mechanically by various lengths of pins, the first pin representing the tens place, and the second pin the units place. For instance, $6 \times 7 = 42$ is represented by a pin in the tens place whose length is 4, and another pin in the units place whose length is 2. The scheme indicated, namely, the representation of the multiplication table by different lengths of pins, was the one first proposed as a mechanical representation of the multiplication table, and was brought out by Leon Bollée, a Frenchman, many years ago—I think in 1896. After him there came many others. Kindly notice that in a multiplication-table multiplying machine it is necessary to perform two additions for each decimal place, namely, the addition of the figures in the tens place and the addition of the figures in the units place. This would seem to indicate that the multiplication-table multiplying machine requiring only two additions per decimal place is about two and a half times as fast as the repeated-addition multiplying machines, which require five additions on the average for each decimal place. In practice, however, the difference is considerably reduced by the special mechanism that must be operated in the multiplication-table multiplying machines, and which do not occur in the repeated-addition multiplying machines.

The above refers to the multiplication of a multiplicand by a multiplier of a single figure, say, 4896 by 7. In case the multiplier has more than one figure, it is necessary to move some portion of the mechanism relatively to another to thereby shift the decimal place. This is accomplished on most machines by hand, but on the Moon-Hopkins and Millionaire machines it is accomplished automatically.

Dividing Machines.—Division is ordinarily accomplished mentally by guessing at a trial divisor, attempting the division, seeing whether it is right or wrong, and correcting the result in accordance therewith. This guessing process has not been followed mechanically; in the machines that divide, division is accomplished by continuous subtraction of the divisor and the determination when that divisor has been subtracted a sufficient number of times. In the machines on the market this determination occurs whenever the remainder obtained by the continuous subtraction of the divisor from the dividend becomes negative. That is, it occurs just one step too late. This necessitates one retracing step to correct the error just introduced. The machines, therefore, operate as follows:

Subtract, subtract continually until the remainder becomes negative. This is now one step too far. Therefore, add once to correct this last wrong subtraction and then step down one decimal place, and repeat the process.

In some machines on the market the operator has to watch to see when the remainder will become negative. In others, namely, the Millionaire, the Brunsviga, the



Section Through 7

Fig. 17

Thales, the Marchand, etc., an audible signal is given by ringing a bell whenever the remainder becomes negative.

You will, therefore, notice that only a [illegible] multiplying machine can be readily used as a dividing machine.

The Birth-Time of the World*

Methods of Determining Its Age

By Prof. J. Joly, Sc.D., F.R.S.

Of our earth's origin we have no certain knowledge; nor can we assign any date to it. Possibly its formation was an event so gradual that the beginning was spread over immense periods. We can only trace the history back to certain events which may with considerable certainty be regarded as ushering in our geological era.

Notwithstanding our limitations the date of the birth-time of our geological era is the most important date in science. For in taking into our minds the spacious history of the universe it must play the part of time-unit upon which all our conceptions depend. If we date the geological history of the earth by thousands of years, as did our forerunners, we must shape our ideas of planetary time accordingly; and the duration of our solar system, and of the heavens, becomes comparable with that of the dynasties of ancient nations. If in millions of years the sun and stars are proportionately venerable. If in hundreds or thousands of millions of years the human mind must consent to correspondingly vast epochs for the duration of material changes. The geological age plays the same part in our views of the duration of the universe as the earth's orbital radius does in our views of the immensity of space.

A study of the rocks shows us that the world was not always what it now is and long has been. We live in an epoch of denudation. The rains and frosts disintegrate the hills; and the rivers roll to the sea the finely divided particles into which they have been resolved; as well as the salts which have been leached from them. The sediments collect near the coasts of the continents; the dissolved matter mingles with the general ocean. The geologist has measured and mapped these deposits and traced them back into the past, layer by layer. He finds them ever the same: sandstone, slates, limestones, etc. But one thing is not the same. *Life* grows ever less diversified in character as the sediments are traced downwards. Mammals and birds, reptiles, amphibians, fishes, die out successively in the past; and barren sediments ultimately succeed, leaving the first beginnings of life undecipherable. Beneath these barren sediments lie rocks collectively differing in character from those above; mainly volcanic or poured out from fissures in the early crust of the earth. Sediments are scarce among these materials.[1]

There can be little doubt that in this underlying floor of igneous and metamorphic rocks we have reached those surface materials of the earth which existed before the long epoch of sedimentation began, and before the seas came into being. They formed the floor of a vaporised ocean upon which the waters condensed here and there from the hot and heavy atmosphere. Such were the probable conditions which preceded the birth-time of the ocean and of our era of life and its evolution.

It is from this epoch we date our geological age. Our next purpose is to consider how long ago, measured in years, that birth-time was.

THE AGE BY THE THICKNESS OF THE SEDIMENTS.

The earliest recognized method of arriving at an estimate of the earth's geological age is based upon the measurement of the collective sediments of geological periods, and consists in measuring the depths of all the successive sedimentary deposits where these are best developed. The total of these measurements would tell us the age of the earth if their tale was indeed complete, and if we knew the average rate at which they have been deposited. Thus it is not easy to measure the real thickness of a deposit. It may be folded back upon itself, and so we may measure it twice over. We may exaggerate its thickness by measuring it not quite straight across the bedding or by unwittingly including volcanic materials. On the other hand, there may be deposits which are inaccessible to us; or, again, an entire absence of deposits; either because not laid down in the areas we examine, or, if laid down, again washed into the sea. These sources of error in part neutralise one another. Some make our resulting age too long, others make it out too short. But we do not know if a balance of error does not still remain. Here, however, is a table of deposits which summarises a great deal of our knowledge of the thickness of the stratigraphical accumulations. It is due to Prof. Sollas.[3]

		Feet.	
Recent and Pleistocene		4,000	
Pliocene		13,000	
Miocene		14,000	
Oligocene		12,000	
Eocene		20,000	
			63,000
Upper Cretaceous		24,000	
Lower Cretaceous		20,000	
Jurassic		8,000	
Trias		17,000	
			69,000
Permian		12,000	
Carboniferous		29,000	
Devonian		22,000	
			63,000
Silurian		15,000	
Ordovician		17,000	
Cambrian		26,000	
			58,000
Keweenawan	Algonkian	50,000	
Animikian		14,000	
Huronian		18,000	
			82,000
Archæan		?	
Total			335,000 feet

In the next place we require to know the average rate at which these rocks were laid down. This is really the weakest link in the chain. The most diverse results have been arrived at, which space does not permit us to consider. The value required is most difficult to determine, for it is different for the different classes of material, and varies from river to river according to the conditions of discharge to the sea. We may probably take it as between two and six inches in a century.

Now the total depth of the sediments as we see is about 335,000 feet (or 64 miles), and if we take the rate of collecting as 3 inches in a hundred years we get the time for all to collect as 134 millions of years. If the rate be 4 inches, the time is 100 millions of years, which is the figure Geikie favored, although his result was based on somewhat different data. Sollas most recently finds 80 millions of years.[4]

THE AGE BY THE MASS OF THE SEDIMENTS.

In the above method we obtain our result by the measurement of the *linear* dimensions of the sediments. These measurements, as we have seen, are difficult to arrive at. We may, however, proceed by measurements of the *mass* of the sediments, and then the method becomes more definite. The new method is pursued as follows:

The total mass of the sediments formed since denudation began may be ascertained with comparative accuracy by a study of the chemical composition of the waters of the ocean. The salts in the ocean are undoubtedly derived from the rocks, increasing age by age as the latter are degraded from their original character under the action of the weather, etc., and converted to the sedimentary form. By comparing the average chemical composition of these two classes of material—the primary or igneous rocks and the sedimentary—it is easy to arrive at a knowledge of how much of this or that constituent was given to the ocean by each ton of primary rock which was denuded to the sedimentary form. This, however, will not assist us to our object unless the ocean has retained the salts shed into it. It has not generally done so. In the case of every substance but one only, the ocean continually gives up again more or less of the salts supplied to it by the rivers. The one exception is the element sodium. The great solubility of its salts has protected it from abstraction, and it has gone on collecting during geological time, practically in its entirety. This gives us the clue to the denudative history of the earth.[4] It is the secret of the sea.

The process is now simple. We estimate by chemical examination of igneous and sedimentary rocks the amount of sodium which has been supplied to the ocean per ton of sediment produced by denudation. We also calculate the amount of sodium contained in the ocean. We divide the one into the other (stated, of course, in the same units of mass), and the quotient gives us the number of tons of sediment. The most recent estimate of the sediments made in this manner affords 50×10^{16} tonnes.[5]

Now we are assured that all this sediment was transported by the rivers to the sea during geological time. Thus it follows that if we can estimate the average annual rate of the river supply of sediments to the ocean over the past we can calculate the required age. Now the land surface is at present largely covered with the sedimentary rocks themselves. Sediment derived from these rocks must be regarded as, for the most part, purely cyclical; that is, circulating from the sea to the land and back again. It does not go to increase the great body of detrital deposits. We cannot, therefore, take the present river supply of sediment as representing that obtaining over the long past. If the land was all covered still with primry rocks we might do so. It has been estimated that about 25 per cent of the existing continental area is covered with archæan and igneous rocks, the remainder being sediments.[6] On this estimate we may find valuable major and minor limits to the geological age. If we take 25 per cent only of the present river supply of sediment, we evidently fix a major limit to the age, for it is certain that over the past there must have been on the average a faster supply. If we take the entire river supply, on similar reasoning we have what is undoubtedly a minor limit to the age.

The river supply of detrital sediment has not been very extensively investigated, although the quantities involved may be found with comparative ease and accuracy. The following table embodies the results obtained for some of the leading rivers.[7]

	Mean annual discharge in cubic ft. per second	Total annual sediment in thousands of tons.	Ratio of sediment to water by weight.
Potomac	20,160	5,557	1 : 3,575
Mississippi	610,000	406,250	1 : 1,500
Rio Grande	1,700	3,830	1 : 291
Uruguay	150,000	14,782	1 : 10,000
Rhone	65,850	36,000	1 : 1,775
PO	62,200	67,000	1 : 900
Danube	315,200	108,000	1 : 2,880
Nile	113,000	54,000	1 : 2,050
Irrawaddy	475,000	291,430	1 : 1,610
Mean	201,468	109,650	1 : 2,731

We see that the ratio of the weight of water to the weight of transported sediment in six out of the nine rivers does not vary widely. The mean is 2,730 to 1. But this is not the required average. The water-discharge of each river has to be taken into account. If we ascribe to the ratio given for each river the weight proper to the amount of water it discharges, the proportion of weight of water to weight of sediment, for the whole quantity of water involved, comes out as 2,520 to 1.

Now if this proportion holds for all the rivers of the world—which collectively discharge about 27×10^{15} tonnes of water per annum—the river-born detritus is 1.07×10^{13} tonnes. To this an addition of 11 per cent has to be made for silt pushed along the river bed.[8] On these figures the minor limit to the age comes out as 47 millions of years, and the major limit as 188 millions. We are here going on rather deficient estimates, the rivers involved representing only some 6 per cent of the total river supply of water to the ocean. But the result is probably not very far out.

We may arrive at a probable age lying between the major and minor limits. If, first, we take the arithmetic mean of these limits, we get 117 millions of years. Now this is almost certainly excessive, for we here assume that the rate of covering of the primary rocks by sediments was uniform. It would not be so however, for the rate of supply of sediment must have been continually diminishing during geological time, and hence we may take it the rate of advance of the sediments on the primary rocks has also been diminishing. The average rate of supply has therefore been greater than the mean rate. Now we may probably take, as a fair assumption, that the sediment-covered area was at any instant increasing at a rate proportionate to the rate of supply of sediment; that is, to the area of primary rocks then exposed. On this assumption the age is found to be 87 millions of years.

THE AGE BY THE SODIUM OF THE OCEAN.

I have next to lay before you a quite different method. I have already touched upon the chemistry of the ocean, and on the remarkable fact that the sodium contained in it has been preserved, practically, in its entirety from the beginning of geological time.

* Delivered before the Royal Dublin Society, reprinted from Science Progress.

[5] Clarke, *A Preliminary Study of Chemical Denudation* (Washington 1910). My own estimate in 1899 (*loc. cit.*) made as a test of yet another method of finding the age, showed that the sediments may be taken as sufficient to form a layer 1 1 mile deep if spread uniformly over the continents; and would amount to 64×10^{16} tons.

[6] Van Tillo, *Comptes Rendues* (Paris), vol. cxiv. 1892.

[7] Russell, *River Development* (John Murray, 1898).

[8] According to observations made on the Mississippi (Russell, *loc. cit.*)

There is little doubt that the primeval ocean was in the condition of a fresh water lake It can be shown that a primitive and more rapid solution of the original crust of the earth by the slowly cooling ocean would have given rise to relatively small salinity The fact is the quantity of salts in the ocean is enormous We are only now concerned with the sodium but if we could extract all the rock salt (the chloride of sodium) from the ocean we would have enough to cover the entire dry land of the earth to a depth of 400 feet It is this gigantic quantity which is going to enter into our estimate of the earth s age The calculated mass of sodium contained in this rock-salt is 14 130 million million tonnes

If now we can determine the rate at which the rivers supply sodium to the ocean we can determine the age [7] As the result of many thousands of river analyses the total amount of sodium annually discharged to the ocean by all the rivers of the world is found to be probably not far from 175 million tonnes [8] Dividing this into the mass of oceanic sodium we get the age as 80 7 millions of years Certain corrections have to be applied to this figure which result in raising it to a little over 90 millions of years By this method Sollas gets the age as between 80 and 150 millions of years My own result was between 80 and 90 millions of years but I subsequently found that upon certain extreme assumptions a maximum age might be arrived at of 105 millions of years [10] Clarke regards the 80 7 millions of years as certainly a maximum in the light of certain calculations by Becker [11]

The order of magnitude of these results cannot be shaken unless on the assumption that there is something entirely misleading in the existing rate of solvent denudation On the strength of the results of another and entirely different method of approaching the question of the earth s age (which shall be presently referred to) it has been contended that it is too low It is even asserted that it is from nine to fourteen times too low We have then to consider whether such an enormous error can enter into the method The measurements involved cannot be seriously impugned Corrections for possible errors applied to the quantities entering into this method have been considered by various writers My own original corrections have been generally confirmed I think the only point left open for discussion is the principle of uniformitarianism involved in this method and in the methods previously discussed

In order to appreciate the force of the evidence for uniformity in the geological history of the earth it is of course necessary to possess an acquaintance with that history Some of the most eminent geologists among whom Lyle and Geikie [12] may be mentioned have upheld the doctrine of uniformity It must here suffice to dwell upon a few points having special reference to the matter under discussion

The mere extent of the land surface does not within limits affect the question of the rate of denudation This arises from the fact that the rain supply is quite insufficient to denude the whole existing land surface About 30 per cent of it does not in fact drain to the ocean If the continents become invaded by a great transgression of the ocean this rainless area diminishes and the denuded area advances inward without diminution If the ocean recedes from the present strand lines the rainless area advances outward but the rain supply being sensibly constant no change in the river supply of salts is to be expected

Age-long submergence of the entire land or of any very large proportion of what now exists is negatived by the continuous sequence of vast areas of sediment in every geological age from the earliest times Now sediment-receiving areas always are but a small fraction of those exposed areas whence the sediments are supplied [13] Hence in the continuous records of the sediments we have assurance of the continuous exposure of the continents above the ocean surface The doctrine of the permanency of the continents has in its main features been accepted by the most eminent authorities As to the actual amount of land which was exposed during past times to denudative effects no data exist to show it was very different from what is now exposed It has been estimated that the average area of the North American continent over geologic time was about eight-tenths of its existing area [14] Restorations of other continents so far as they have been attempted would not suggest any more serious divergency one way or the other

That climate in the oceans and upon the land was throughout much as it is now the continuous chain of teeming life and the sensitive temperature limits of protoplasmic existence are sufficient evidence [15] The influence at once of climate and of elevation of the land may be appraised at their true value by the ascertained facts of solvent denudation as the following table shows

	Tonnes removed in solution per square mile per annum	Mean elevation Meters
North America	79	700
South America	50	650
Europe	100	300
Asia	84	950
Africa	44	650

In this table the estimated number of tonnes of matter in solution which for every square mile of area the rivers convey to the ocean in one year is given in the first column These results are compiled by Clarke from a very large number of analyses of river waters The second column of the table gives the mean heights as meters above sea level of the several continents in cited by Arrhenius [16]

Of all the denudation results given in the table those relating to North America and to Europe are far the most reliable These show that Europe with a mean altitude of less than half that of North America sheds to the ocean 25 per cent more salts Hence if it is true as has been stated that we now live in a period of exceptionally high continental elevation we must infer that the average supply of salts to the ocean by the rivers of the world is less than over the long past and that therefore our estimate of the age of the earth as already given is excessive

There is however one condition which will operate to unduly diminish our estimate of geologic time and it is a condition which may possibly obtain at the present time If the land is on the whole now sinking relatively to the ocean level the denudation area tends as we have seen to move inwards It will thus encroach upon regions which have not for long periods drained to the ocean On such areas there is an accumulation of soluble salts which the deficient rivers have not been able to carry to the ocean Thus the salt content of certain of the rivers draining to the ocean will be influenced not only by present denudative effects but also by the stored results of past effects Certain rivers appear to reveal this unduly increased salt supply those which flow through comparatively arid areas However the flow-off of such tributaries is relatively small and the final effects on the great rivers apparently unimportant —a result which might have been anticipated when the extremely slow rate of the land movements is taken into account

The difficulty of effecting any reconciliation of the methods already described and that now to be given increases the interest both of the former and the latter

THE AGE BY RADIOACTIVE TRANSFORMATIONS

Rutherford suggested in 1905 that as helium was continually being evolved at a uniform rate by radioactive substances (in the form of the alpha rays) a determination of the age of minerals containing the radioactive elements might be made by measurements of the amount of the stored helium and of the radioactive elements giving rise to it The parent radioactive substance is —according to present knowledge—uranium or thorium. An estimate of the amounts of these elements present enables the rate of production of the helium to be calculated Rutherford shortly afterwards found by this method an age of 240 millions of years for a radioactive mineral of presumably remote age Strutt who carried his measurements to a wonderful degree of refinement found the following ages for mineral substances originating in different geological ages

Oligocene	8 4	millions of years.
Eocene	31	
Lower Carboniferous	150	
Archæan	710	

Another product of radioactive origin is lead The suggestion that this substance might be made available to determine the age of the earth also originated with Rutherford We are at least assured that this element cannot escape by gaseous diffusion from the minerals. Boltwood s results on the amounts of lead contained in minerals of various ages, taken in conjunction with the amount of uranium or parent substance present, afforded ages rising to 1 640 millions of years for Archæan and 1 200 millions for Algonkian time Becker applying the same method obtained results rising to quite incredible periods from 1 671 to 11 470 millions of years. Becker maintained that original lead rendered the determinations indefinite. The more recent results of Mr A Holmes support the conclusion that original lead may be present and may completely falsify results derived from minerals of low radioactivity in which the derived lead would be small in amount By rejecting such results as appeared to be of this character he arrives at 370 millions of years as the age of the Devonian.

I must now describe a very recent method of estimating the age of the earth There are in certain rock-forming minerals color-changes set up by radioactive effects The minute and curious marks so produced are known as haloes for they surround in ring-like forms minute particles of included substances which contain radioactive elements The particle in the center of the halo contains uranium or thorium and necessarily along with the parent substance the various elements derived from it In the process of transformation giving rise to these several derived substances atoms of helium, projected with great velocity into the surrounding mineral—the alpha rays—occasion the color changes referred to These changes are limited to the distance to which the alpha rays penetrate hence the halo is a spherical volume surrounding the central substance [17]

The time required to form a halo can be found if on the one hand we could ascertain the number of alpha rays ejected in say one year from the nucleus of the halo and on the other if we determine by experiment just how many alpha rays were required to produce the same amount of color alteration as we perceive to extend around the nucleus

The latter estimate is fairly easily and surely made But to know the number of rays leaving the central particle in unit time we require to know the quantity of radioactive material in the nucleus This cannot be directly determined We can only from known results obtained with larger specimens of just such a mineral substance as composes the nucleus guess at the amount of uranium or it may be thorium which may be present

This method has been applied to the uranium haloes of the mica of County Carlow [18] Results for the age of the halo of from 20 to 400 millions of years have been obtained This mica was probably formed in the granite of Leinster in late Silurian or in Devonian times

The higher results are probably the least in error upon the data involved for the assumption made as to the amount of uranium in the nuclei of the haloes was such as to render the higher results the more reliable

This method is of course a radioactive method and similar to the method by helium storage save that it is free of the risk of error by escape of the helium the effects of which are as it were registered at the moment of its production so that its subsequent escape is of no moment

REVIEW OF THE RESULTS

By methods based on the approximate uniformity of denudative effects in the past, a period of the order of 100 millions of years has been obtained as the duration of our geological age and consistently whether we accept for measurement the sediments or the dissolved sodium We can give reasons why these measurements might afford too great an age but we can find absolutely no good reason why they should give one much too low

By the storage of radioactive products ages have been found which, while they vary widely among themselves yet claim to possess accuracy in their superior limits and exceed those derived from denudation from nine to fourteen times.

In this difficulty let us consider the claims of the radioactive method in any of its forms In order to be trustworthy it must be true (1) that the rate of transformation now shown by the parent substance has obtained throughout the entire past and (2) that there were no other radioactive substances, either now or formerly existing except uranium, which gave rise to lead As regards methods based on the production of helium what we have to say will largely apply to it also If some unknown source of these elements exists we, of course on our assumption over-estimate the age.

As regards the first point In ascribing a constant ratio of change to the parent substance—which Becker (loc. cit) describes as a simple though tremendous extrapolation —we reason upon analogy with the constant rate of decay observed in the derived radioactive bodies. If uranium and thorium are really primary [illegible]

[7] Trans R D S 1899 A paper by Edmund Halley the astronomer in the *Philosophical Transactions of the Royal Society* for 1715 contains a suggestion for finding the age of the world on somewhat similar lines He proposes to make observations on the saltness of the seas and ocean at intervals of one or more centuries and from the increment of saltness arrive at their age The measurements as a matter of fact are impracticable The salinity would only gain (if all remained in solution) one millionth part in 100 years and of course the continuous rejection of salts by the ocean would invalidate the method The last objection also invalidates the calculation by T Mellard Reade (*Proc Liverpool Geol Soc* 1876) of a minor limit to the age by the calcium sulphate in the ocean Both papers were quite unknown to me when working out my method Halley s paper was I think only brought to light in 1908

[17] Phil. Mag., March, April and February 1907; also [illegible] January, 1912.

[18] Joly and Rutherford, Phil. Mag., July 1913.

however, the analogy relied on may be misleading at least, it is obviously incomplete It is incomplete in a particular which may be very important the mode of origin of these parent bodies—whatever it may have been —is different to that of the secondary elements with which we compare them A convergence in their rate of transformation is not impossible or even improbable so far as we know

As regards the second point It is assumed that uranium alone of the elements in radioactive minerals is ultimately transformed to lead by radioactive changes We must consider this assumption.

Recent advances in the chemistry of the radioactive elements have brought out evidence that all three lines of radioactive descent known to us—i e those beginning with uranium, with thorium and with actinium—alike converge to lead [12] There are difficulties in the way of believing that all the lead-like atoms so produced ("isotopes" of lead, as Mr Soddy proposes to call them) actually remain as stable lead in the minerals For one thing there is sometimes along with very large amounts of thorium an almost entire absence of lead in thorianites and thorites And in some urano-thorites the lead may be noticed to follow the uranium in approximate proportionality notwithstanding the presence of large amounts of thorium [13] This favors the assumption that all the lead present is derived from the uranium The actinium is present in negligibly small amounts

[12] See Soddy's *Chemistry of the Radioactive Elements* (Longmans Green & Co)

[13] It seems very difficult at present to suggest an end product for thorium unless we assume that by loss of electrons thorium E or thorium-lead reverts to a substance chemically identical with thorium itself Such a change—whether considered from the point of view of the periodic law or of the radioactive theory—would involve many interesting consequences It is of course quite possible that the nature of the conditions attending the deposition of the uranium ores many of which are comparatively recent are responsible for the difficulties observed The thorium and uranium ores are, again specially prone to alteration

On the other hand there is evidence arising from the atomic weight of lead which seems to involve some other parent than uranium Mr Soddy in the work referred to points this out The atomic weight of radium is well known and uranium in its descent has to change to this element The loss of mass between radium and uranium-derived lead can be accurately estimated by the number of alpha rays given off From this we get the atomic weight of uranium-derived lead as closely 206 Now the best determinations of the atomic weight of normal lead assign to this element an atomic weight of closely 207 By a somewhat similar calculation it is deduced that thorium-derived lead would possess the atomic weight of 208 Thus normal lead might be an admixture of uranium and thorium-derived lead However as we have seen the view that thorium gives rise to stable lead is beset with some difficulties

If we are going upon reliable facts and figures we must then assume (*a*) That some other element than uranium and genetically connected with it (probably as parent substance) gives rise or formerly gave rise to lead of heavier atomic weight than normal lead It may be observed respecting this theory that there is some support for the view that a parent substance both to uranium and thorium has existed or possibly exists The evidence is found in the proportionality frequently observed between the amounts of thorium and uranium in the primary rocks [14] Or (*b*) We may meet the difficulties in a simpler way which may be stated as follows If we assume that all lead is derived from uranium and at the same time recognise that lead is not perfectly homogeneous in atomic weight we must of necessity ascribe to uranium a similar want of homogeneity heavy atoms of uranium giving rise to heavy atoms of lead and light atoms of uranium generating light atoms of lead This assumption seems to be involved in the figures upon which we are going Still relying on these figures we find however that existing uranium cannot give rise to lead of normal atomic weight We can only conclude that the heavier atoms of uranium have decayed more rapidly than the lighter ones In this connection it is of interest to note the complexity of uranium as recently established by Geiger although in this case it is assumed that the shorter lived isotope is genetically unconnected with the longer-lived and largely preponderating constituent There does not seem to be any direct proof of this as yet however

[14] Compare results for the thorium content of such rocks (appearing in a paper by the author *Cong Int de Radiologie et d Electricité* vol 1 1910 p 373) and those for the radium content as collected in *Phil Mag* October 1912 p 697

From these considerations it would seem that unless the atomic weight of lead in uraninites etc is subnormal the former complexity and more accelerated decay of uranium are involved in the data respecting the atomic weights of radium and lead and the radioactive events which occur in the transmutation of the one into the other As an alternative view we may assume as in our first hypothesis that some elementally different but genetically connected substance decaying along branching lines of descent at a rate sufficient to practically remove the whole of it during geological time formerly existed Whichever hypothesis we adopt we are confronted by probabilities which invalidate time-measurements based on the lead and helium ratio in minerals We have in short grave reason to question the measure of uniformitarianism postulated in finding the age by any of the known at present radioactive methods

That we have much to learn respecting our assumptions whether we pursue the geological or the radioactive methods of approaching the age of our era is indeed probable Whatever the issue it is certain that the reconciling facts will leave us with much more light than we at present possess either as respects the earth's history or the history of the radioactive elements

Sea-Salt and Geologic Time*

A Discussion of Prof. Joly's Method of Determining the Age of the World

By H S Shelton, B Sc

The present short article is a reversion to an aspect of the subject of geologic time which I had thought to be settled and to require no further research or controversy In my review of Mr Holmes's book I commented strongly on his ignorance of current literature I now find that the same imperfect acquaintance with recent discussion and research is shared by the writer who is responsible for putting forward the amount of sodium in the sea as an index of geologic time I assume of course that ignorance is the explanation for I take it that no man of science of recognized position when the errors of his research had been pointed out would deliberately ignore the fact and proceed as if his work was a valid contribution to the advancement of science My excuse, therefore for writing an article containing nothing material which I have not previously published is the following passage for which Sir Ernest Rutherford and Prof Joly are jointly responsible

But it is certain that if the higher values so found are reliable the discrepancy with estimates of the age of the ocean based on the now well-ascertained facts of solent denudation raises difficulties which at present seem inexplicable [1]

The values of geologic time referred to based on radioactive methods especially the age of pleochroic haloes, I propose to criticise on a future occasion There are good grounds which cannot be stated here for thinking that all attempts to assess exact times for particular geologic epochs by calculation either of the lead ratios of uranium minerals or otherwise are premature, and are based on an imperfect realisation of the complexity of the subject The object of the present article, however, is to repeat[2] the arguments which show that the alternative method based on the salt-content of the ocean is of no value whatever Not only is the discrepancy not inexplicable, there is no discrepancy to explain. So much did I take this for granted that, in my last article on the subject [4] I did not think it necessary to consider the sea-salt method. I therefore take this opportunity to repeat the arguments, and to remedy what is apparently a deficiency

Prof. Joly's original paper[5] was based on the supposed facts (1) that as roughly estimated by Sir John Murray of the solid matter dissolved in river water which reaches the sea 3 47 per cent is sodium (2) that nearly all this hypothetical sodium is obtained by erosion of the rocks (3) that when this hypothetical sodium reaches the sea none of it returns to the rocks On this supposition dividing the amount of sodium in the sea by the amount which reaches it each year an estimate of geologic time could be made The objection is briefly that the three supposed facts are merely supposed facts No single one of them is reliable

For convenience we will take the second point first Of the sodium which actually reaches the sea a considerable proportion is associated with chlorine None of the sodium chloride in the rivers can be attributed to erosion This is so for two reasons In the first place it is well known that the proportion of chlorine in the rocks igneous or sedimentary is infinitesimal In the second place the sources of the chlorine have been thoroughly well determined In the main they are two cyclic salt carried by the wind from the sea and salt due to human contamination It has been found possible particularly in New York State to eliminate the cyclic salt the amount of which is a function of the distance from the coast and to show that the residual chlorine in river water is a direct function of density of population Unless you take the sewage from town and country districts directly out to sea the salt in it inevitably reaches the rivers If you obtain an abnormally high chlorine ratio when the sewage is supposed to be carried out to sea the inference is leakage The source which would naturally occur to any one brine-springs has been shown to be negligible Even in New York State where brine-springs are plentiful there is no appreciable effect on the salt content of the rivers [6] The only known means by which fresh chlorine reaches the sea is volcanic action and it is a point open to dispute how much of the volcanic chlorine is not ultimately derived from the sea. It follows therefore that of the sodium which actually reaches the sea only that not associated with the chlorine can be counted

This much Prof Joly and those who agree with his earlier estimate have been willing to admit But Prof Joly maintains that if the chlorine equivalent of the sodium be subtracted there is still sufficient sodium to necessitate an estimate of geologic time less than 150 millions of years. His reason is merely Sir John Murray's rough tabulation of then current analyses and some more recent results It does seem strange however that Prof Joly never troubled to inquire whether there were any water analyses sufficiently accurate for this purpose It is highly probable that Prof Joly's original paper would never have been written if he had understood why water analyses are undertaken and the manner in which they are actually performed Had he been a water analyst or even a chemist the first thing that would have occurred to him would have been that these sodium determinations were decidedly hypothetical Several chemists have expressed doubts as to the validity but such discussions Prof Joly has either ignored or failed to understand[7] It may therefore surprise Prof Joly to be informed that it is doubtful whether the sodium content of any single river water has ever been accurately determined If any such cases have occurred, they are very few Let us imagine that there is in a given sample of river water two parts of sodium per million. Such a proportion would be quite ordinary according to the usual tables It would be a very interesting problem to try to separate this out and weigh it To obtain a good weighable quantity (say 0 05 gram of sodium giving about 0 15 gram of sodium sulphate[8]) would require 25 liters of water the greater part of a carboy and the difficulties in the way of isolating it are such as any chemist can understand

As a matter of fact the accurate determination of the sodium is a form of amusement in which the ordinary water analysts do not indulge Sometimes the alkalis sodium and potassium are determined together by difference that is not determined at all In a paper[9] that has been sent to me recently the analyst describes his methods In this case everything possible is got rid of by the usual methods of precipitation and the remainder is evaporated and weighed as Sodium and Potassium Chlorides The amount dealt with is only that from 250 cubic centimeters of filtered water and would of course be infinitesimal and the fact that it amounts to not more than 2 or 3 per cent of the total dissolved solid is a good indication of the general ac-

[8] In ordinary accurate analysis sodium is usually weighed as sulphate In water analysis however the quantity is so small that conversions to sulphate is not worth while The residue is reckoned as chloride though it need not necessarily be so

[9] The Quality of the Surface Waters of Illinois U S A Geological Survey Water Supply Paper No 239, p 16 The method is the one usually recommended in the text-books See Wanklyn, 11th edition, p. 139.

curacy of the analysis The residue includes of course everything that is not caught by the filter throughout the whole operation It should be mentioned also that the samples usually stand for days in glass bottles In such cases of water analysis when the sodium and the potassium are separated the separation is needless to say, a very approximate operation [10]

It is no reflection on the accuracy of river water analysts to say that the results are of no value whatever for Prof Joly s purpose No one except Prof Joly and a few geologists wants to know the proportion of sodium in river water It is at the same time the constituent least important for the purpose of the water analyst and the constituent most difficult to determine The assumption on which Prof Joly proceeds that 3 47 per cent of the dissolved matter in river water is sodium is absolutely unproven For all the analyses prove it might be less than half that amount Indeed the principal evidence that there is an excess of sodium over and above its equivalent of chlorine is indirect rather than direct The results of rock analyses are more reliable and it seems to be established that the sodium content of igneous rocks is greater than that of the aqueous As a matter of fact it has been pointed out by Prof Dubois that when there is any reason to ascribe special accuracy to river water analyses the excess of sodium diminishes and tends to vanish Prof Dubois collected a number of good analyses tabulated them and inferred from them according to Prof Joly s method a geologic time of 400 million years The inference he made as he was a believer in Lord Kelvin s methods was that the original sea was salt The true inference is that the method is of no value Within the limits of experimental error you can deduce any value you please

Though the previous discussion renders it unnecessary it is as well to mention one other point The assumption that no sodium returns from the sea to the rocks is unwarranted Indeed one instance to the contrary can be mentioned It is a recognized fact that much of the salt in the salt lakes and inferentially in salt beds is windborne and has its origin in the sea But what would occur when strata containing salt beds are subject to metamorphosis or are absorbed by the magma? Is it not obvious that the sodium would be added to the content of the rocks and that the chlorine would be expelled as some volatile compound? Indeed is it not probable that some portion of volcanic chlorine has this origin? Again with regard to the ordinary processes of the formation of sedimentary rock we do not know enough to say that no dissolved sodium is reabsorbed

This speculation however is a side issue and is not necessary to the argument Were the analyses of sufficient accuracy were the method in general valid such matters would require careful consideration At present without taking such remote speculations into account we can still say that the sea-salt method is absolutely worthless It is based on a misapprehension of the data on which it rests It is an instance of the care that is required when results are transferred from one branch of science to another With regard to geologic time the value of radioactive methods is still to be determined The value of the sea-salt method like the still more famous ones of Kelvin and Tait is nil

The Optical Anisotropy of Liquid Crystals*

By B. O Lehman

The underlying purpose of all my work has been the proof of the untenability of the Theory of Identity of the molecule in all forms of a given substance and the discovery of liquid crystals has furnished the direct proof sought

I The untenability of the Theory of Identity

(a) Transformation temperatures Molten ammonium nitrate crystallizes at 161 degrees in very soft, regular crystals at 125 6 degrees these again crystallize into harder tetragonal forms, and so at 82 80 degrees 32 4 degrees and −16 degrees firmer and firmer forms appear Contrary to the Theory of Identity I found on reheating that the melting points were identical with and not higher than these solidification points from which I conclude that polymorphous transformation is a chemical process entailing alteration of the molecule and from this follows the second conclusion that melting and vaporization change the molecule otherwise two different modifications would furnish two different vapors and liquids

(b) The plasticity of crystals According to the Theory of Identity there could be no flowing or true plasticity of crystals nothing but a translation of crystal fragments. My work with ammonium nitrate proved that there do exist plastic crystals, i. e crystals whose fragments are no larger than single molecules. In the case of silver iodide, above 146 degrees no limit of elasticity could be demonstrated, and the "snapping" of the molecules into definite orderly arrangement was very doubtful.

(c) The solubility of distorted crystals If variation in solubility of polymorphous forms is due purely to molecular arrangement, as the Theory of Identity presupposes then plastic distortion of crystals (i. e a disturbance of the molecular arrangement) should alter the solubility This is not found to be the case

Although thoroughly convinced that the Theory of Identity was false, and that the soft regular crystals of ammonium nitrate and silver iodide were truly liquid still I was not able to give actual proof that they possessed no limit of elasticity

II Reinitzer s isotropic liquid with oily streaks

After prolonged research I recognized that Reinitzer s isotropic liquid in which crystals and oily streaks are present is different from the isotropic molten mass, and that in all probability it is an entirely irregularly arranged aggregate of the same molecules of which the crystals and oil streaks consist. This conclusion is another contradiction of the Theory of Identity

III The first liquid crystals

Absolute proof of the existence of liquid crystals I first obtained with ammonium oleate hydrate The polyhedric form of the tiny crystals can be explained only by a more or less disturbed molecular arrangement, and the phenomena of spontaneous homeotropy (the immediate automatic restoration of structure after distortion division or fusion of the crystal units) entirely excludes from the realm of possibility the existence of a limit of elasticity No further proof can be asked for the existence of liquid crystals.

IV Classification of crystalline liquids

From my standpoint the anisotropy of the molecules and not their order of arrangement is the prime factor in determining the classification of a crystalline substance hence I classify liquid and solid crystals exactly alike according to their optical properties (1) Monosymmetrical (2) asymmetrical (3) regular (4) tetragonal and hexagonal (5) rhombic etc

[10] The potassium determination would be the more accurate of the two as the potassium is weighed as Pt + 2KCl A further percentage of inaccuracy would thus be thrown on the sodium.

The Sense of Smell in Insects

The Smithsonian Institution has recently issued a paper by Dr N E McIndoo dealing with the olfactory sense of insects which consists of a general review of this unusually confused subject presenting the views of different authors discussing the seat of the olfactory organs summarizing the author s experiments and citing a large number of scientific treatises on the subject which comprises the first classification of such literature

From the views of very early writers including Aristotle Virgil Pliny and others it is evident that the belief in a sense of smell in insects has long been known and believed generally also that some insects are able to distinguish various odors While it is seldom denied that insects can smell no one has yet ascertained the relative sensitiveness for any particular species nor is the seat of the organs definitely located for all species

The writings discussed are classified according to their viewpoints as to the seat of the olfactory organs which seems to be the main point of disagreement among them One theory which has long since been abandoned was that these organs were located in the spiracles or nostrils of the insects as in the case with the higher animals but it was advocated by assumption rather than experiment as no one has found any nerves or organs which suggest an olfactory function either in the spiracles or in the trachea the windpipe

One author holds that these organs are located in the throats of the various insects one in the mouth cavity several in the feelers attached to the mouth many in the antennæ and so on until nearly every available portion of the insect s anatomy has been suggested by one or another student Dr McIndoo however has proved by experiments that many of these theories are wrong by covering up removing or otherwise eliminating various organs and testing the smell of bees ants and hornets thus treated nearly all of which respond as readily and as quickly to the fraction of a second as normal bees ants and hornets under similar conditions

About one half of his experiments were conducted to disprove the somewhat general belief that the sense of smell of insects is located in the antennæ, the horns or feelers attached to the head constituting the organs of touch To this end the experimenter tested honey bees ants and hornets by removing one or both of their antennæ and noting the results when the insects were subjected to the odors from the essential oils of peppermint, thyme ,and wintergreen. Honey pollen, pennyroyal formic acid from ants etc., were also used in testing the sense of smell

After disproving the theories of all the other writers concerning the seat of the olfactory organs, the author began to search for organs similar to those which he found a few years ago in spiders. These organs were soon found on the legs and wings of all the insects examined Many experiments were performed which proved conclusively to the author that these organs are the true apparatus for receiving odor stimuli in the insects tested.

It is certain that spiders can smell, yet they have no antennæ nor any organs that may be compared to the antennal organs of insects This is another argument against the antennæ being organs of smell All insects either have antennal organs like those of the bees, or modifications of them yet no two authors who have studied them have agreed concerning their function Such chaos can be replaced by facts only when the behavior of the insects investigated is thoroughly studied and when experiments are performed in ways other than on the antennæ alone Then it will be realized that the antennæ can no longer be regarded as a possible seat of the sense of smell in insects.

In conclusion it seems that the organs called the olfactory pores by the author are the true olfactory apparatus in bees ants and hornets and possibly in all insects and that the antennæ play no part in receiving odor stimuli.

SCIENTIFIC AMERICAN SUPPLEMENT

Founded 1876

NEW YORK, SATURDAY, JANUARY 30, 1915

Published weekly by Munn & Company Incorporated
Charles Allen Munn President, Frederick Converse Beach Secretary Orson D Munn Treasurer
all at 361 Broadway New York

Entered at Post Office of New York, N Y as Second Class Matter

The Scientific American Publications

Scientific American Supplement (established 1876) per year $5 00
Scientific American (established 1845) " 3.00
American Homes and Gardens 3 00

The combined subscription rates and rates to foreign countries, including Canada will be furnished upon application

Remit by postal or express money order bank draft or check

Munn & Co., Inc., 361 Broadway, New York

The purpose of the Supplement is to publish the more important announcements of distinguished technologists, to digest significant articles that appear in European publications, and altogether to reflect the most advanced thought in science and industry throughout the world.

Recent Significant Developments in Science and Engineering*

A Review and Explanation of the Most Important Advances

The following brief notes describe what seem to be the most significant developments in several of the sciences and branches of engineering. The subjects selected and the material used in the description are due to various professors in Cornell University all of whom are authorities in the several fields touched upon.

PHYSICS

X Rays and Crystalline Structure.—One of the most interesting developments in modern physics is the recent discovery that Roentgen rays can be reflected and diffracted by means of crystals. As an immediate result of this discovery not only has the true nature of X rays themselves been learned but scientists have been able to explore the inner structure of crystals, learning the arrangement of and measuring the distance between the atoms of which they are built. It even seems as though we may be able to probe still deeper by this means, and to find out how the atoms themselves are made.

From the large amount of experimental evidence obtained in the last two years we have every reason to believe that X rays are electromagnetic waves of extremely short wave length about ten thousand times smaller than those of ordinary visible radiation. To measure these wave-lengths in the usual manner by means of a ruled diffraction grating was therefore out of the question. It occurred to Laue that in the regular arrangement of atoms in a crystal we have gratings whose lines are naturally ruled so closely that their distances are of the same order of magnitude as the wave-lengths of X rays. Messrs. Friedrich and Knipping tried the experiment of passing a fine beam of X rays through a crystal of zinc blende a short distance behind which was placed a photographic plate. Upon developing the negative they found a remarkable group of spots arranged symmetrically about the central image.

But within the past year still more interesting results have been obtained by Prof. W. H. Bragg and his son W. L. Bragg[1] who have used this method to determine the structure of crystals. Mr. W. L. Bragg explained each spot on the photographs as being due to the regular reflection of the beam of X rays from a plane in the crystal which is especially rich in atoms. Thus for instance if the atoms are arranged in the form of a cubical lattice work the rays would be partially reflected from planes which contain a relatively large number of atoms.

The cleavage face of a crystal is very rich in atoms so to test his explanation Mr. Bragg allowed a beam of X rays to fall on a cleavage face of a crystal and found as he had predicted that an image was produced on the photographic plate at the angle of reflection. But he noticed that as the angle of incidence was changed there were certain angles at which the reflection was exceptionally strong. These positions of strong reflection could be explained in only one way as real spectrum lines in the X rays-radiation of definite wave length. This explanation led at once to a definite knowledge of the nature of X rays.

When an X ray pulse strikes the cleavage face of a crystal at a definite angle a part of it is reflected by each layer of atoms. If the angle is of the proper value as determined by the wave length of the train of waves and by the distance between the layers of atoms then the reflected pulses will reinforce each other and produce an especially strong image. This was studied by means of an apparatus in which the intensity of a reflected beam could be made to act on an electroscope whose deflection was measured by microscope.

At this time no one knew whether it was the molecules or the individual atoms which did the reflecting. Whatever the reflecting centers were however there was now a means of finding out how they were arranged in the crystal. Mr. Bragg imagined a number of different arrangements of these centers, and on the theory that each spot in Friedrich and Knipping's photographs was a partial reflection of the primary beam by some plane rich in atoms he calculated where the spots should be found for each arrangement. It was found that nothing but a simple cubical design could account satisfactorily for the spots obtained with such crystals as salt, potassium chloride etc. Thus we find that in a crystal of rock salt the sodium and chlorine atoms are arranged in the form of a cubical lattice work with chlorine and sodium atoms situated in alternate corners of the cubes so that for example the sodium atom has six neighboring chlorine atoms equally close with which it might pair off to form a molecule of NaCl. It was calculated that with this arrangement the distance between atoms was a trifle over one hundredth millionth of an inch. It is interesting to note that in this arrangement there is no evidence that the atoms are combined into molecules. A sodium atom is no more closely connected with one particular chlorine atom than with any other.

In much the same way Prof. W. H. Bragg has determined the structure of the diamond. In this case the atoms are all of the same kind—carbon. Each atom may be thought of as bound to four other atoms, arranged at the corners of a tetrahedron. This is in accord with the fact that carbon has four chemical bonds and is in good agreement with the structure of the diamond as determined by the methods of crystallography.

We are getting a glimpse, as it were into the inner most structure of the molecules and are learning daily more and more about the manner in which their constituent atoms are bound together.

Electrical Resistance as Affected by Very Low Temperatures.—The recent experiments performed by Prof. H. Kamerlingh Onnes at the Leiden Physical Laboratory on the electrical resistance of metals at low temperatures have excited wide interest due to the unexpected results obtained. For this work Prof. Onnes has at his command equipment which enables him to obtain temperature within 1.7 deg. Cent. of absolute zero and he can maintain these temperatures for considerable periods of time. He has been studying for some time the electrical properties of metals at low temperatures, and the following is a brief outline of the results of the work as far as reported.

It is well known that the resistance of a metal varies so as to be approximately proportional to the absolute temperature. It is found, however that at low temperatures slight amounts of impurities cause deviation from this law. Cooling an extremely pure sample of mercury Prof. Onnes discovered that at a temperature of about 4.2 deg. Cent. above absolute zero the resistance suddenly became too small to be measured. Just before this change occurred the resistance was 0.002 of the resistance at the melting point. At this temperature the resistance became less than 0.000001 of that resistance. Since, he has found the same phenomena in lead and tin. In lead the change occurs at about 6.1 deg. Cent. and in tin at 3.8 deg. Cent. above absolute zero. Below these critical temperatures the metal seems to have no electrical resistance and Prof. Onnes describes this state by the term "supraconductive." The temperature at which a conductor becomes supraconductive is not the same for all values of current but is lower for larger currents. The resistance is therefore dependent upon the current and Ohm's law no longer holds. Other peculiarities of a supraconductor are worthy of mention since the resistance is immeasurably small there is neither any potential drop in the supraconductor nor is any heat developed.

This is well illustrated as follows. The value of the current in a circuit does not instantly become zero when the generator ceases to deliver power but decreases at a rate which depends upon the self induction and resistance of the circuit. The current cannot become zero until all the energy which is stored in its magnetic field has been transferred into heat by the resistance. The length of time for which such a current has a measurable value is extremely short in most cases. If, however, the resistance of the circuit is made very small, the current will be maintained longer before its energy is transformed and we might imagine the limiting case where the resistance was zero and the current continued to flow, requiring no generator to maintain it because it was expending none of its energy. This case seems to have been realized by Prof. Onnes. A closed coil of 1,000 turns of lead wire was cooled to a temperature of about 1.7 deg. Cent. above absolute zero and an electric current of 0.4 amperes induced in it by the removal of an electromagnet whose flux had previously passed through the coil. Prof. Onnes was able to maintain the coil at this temperature for 3 hours and 20 minutes and was unable to detect any diminution in the value of the current which was measured by the magnetometer method. At the end of this time the temperature rose to a value of 4.3 deg. Cent. (absolute) and as a result the current fell to 0.36 ampere, but the temperature again being reduced the current remained constant for 1 hour and 30 minutes more. As a result of his experiments up to the present time, Prof. Onnes estimates that the resistance of lead in the supraconductive state cannot be greater than $1/(4\times10^{10})$ part of its resistance at ordinary temperatures.

That these results will have an important bearing upon the theories of electrical conduction and molecular magnets there can be no doubt. They also suggest the possibility of being able to obtain by means of supraconductors much stronger magnetic fields than has hitherto been possible.

CHEMISTRY

The field of chemistry is of such nature that it is difficult to select particular discoveries or developments as being the most significant. The following items however are of some interest and importance.

J. N. Pring has devised a method for the determination of ozone at very great dilutions and low temperatures. By this method it has been found that at a height of about 3.0 kilometers the amount of ozone averaged 2.5×10^{-8} parts while at the height of 3.6 kilometers it averaged 4.7×10^{-8} parts. This last amount of ozone was found by colorimetric methods to give a distinct blue color indicating that ozone may be a factor in producing the blue color of the sky.

It has been found that metallic salts are dissociated at the temperature of the Bunsen flame, with the result that the metal is set free. This has made possible the preparation of metallic mirrors of copper, cadmium tin silver, lead, bismuth, zinc, arsenic and antimony by precipitation from the Bunsen flame and also the obtaining of mercury in drops.

Mme. Curie has shown that the inactive end products of the radio active elements uranium, radium, thorium and actinium are elements which, although occupying the position of lead in the periodic system show differing atomic weights. Among the numerous contributions made during the past year in the field of radio-chemistry are interesting articles entitled "Forces between atoms and chemical affinity" by J. J. Thompson and "The structure of the atom" by E. Rutherford.

The controversy regarding the alleged formation of active nitrogen by the electric discharge has finally reached a settlement. The principal investigators now agree that a sample of nitrogen may indeed be made to give the glow more readily when containing a trace of oxygen but that the purest nitrogen is also capable of giving a brilliant glow. The presence of infinitesimal traces of oxygen seems to be favorable to the production of active nitrogen.

Sir William Crookes has measured the spectrum of the purest obtainable (99.98 per cent) elementary silicon. G. W. Morey has prepared four new crystalline alkaline silicates. In addition to the crystalline products, a series of hydrous glasses was obtained. They are perfectly hard even though containing up to 25 per cent water."

MATHEMATICS

The most valuable recent contribution is that of systematizing processes of numerical and graphical approximation. A well known older example of this process is illustrated by Hörner's method for finding (approximately) the numerical roots of an algebraic equation.

Owing chiefly to the activity of Prof. Carl Runge, of the University of Göttingen, a similar process can be applied to a large category of problems, including Fourier's Series, graphical integration, solution of differential equations which define the flow of heat, electricity, etc., adjustment of errors of observation and other problems. Two years ago Prof. Runge gave a course of lectures at Columbia University in which many of his ideas were developed. Since then a considerable number of young men have been working out particular problems connected with it. These are only partly available as yet, the only book being one just published in German, by Dr. H. v. Sanden, also of Göttingen. It is called "Praktische Analysis." Other volumes of the same series with this same [illegible] are already in the press. Other applications of this principle are the [illegible] of the uses of the [illegible] and calculating machines, and its application in the field of descriptive geometry.

* *Sibley Journal of Engineering.*

[1] Prof. W. H. Bragg F.R.S. Professor of Physics and Mathematics at Leeds University England gave a special lecture on "X rays and Crystalline Structure" before Cornell University on December 2nd 1914 under the auspices of the Sigma Xi Society. The above article is a brief abstract of this lecture. For more detailed information see contributions by Prof. W. H. Bragg and W. L. Bragg in the *Proc. Roy. Soc.* 89 pp. 248-291 (1913) and more recent subsequent articles.

ELECTRICAL ENGINEERING

Wireless Transmission—The use of sustained or undamped waves in wireless transmission has long been recognized to offer a large number of important advantages, but the generation of these waves has always been a source of difficulty To produce an alternator of any considerable capacity which will directly generate voltages with a frequency of around 50,000 cycles is an extremely difficult proposition due to obvious mechanical and electrical difficulties

A great many of these limitations have been overcome in the Goldschmidt "reflection' alternator such as is now operating in the transatlantic radio station at Tuckerton, N J

The fundamental frequency of this alternator is about 10,000 cycles, but by an ingenious system of reflection and resonance between the two windings, the output is delivered at a frequency of 40 000 cycles The machine is of German construction and especially rigid in design. The rotor of the alternator is driven by a 250 horse-power direct-current motor, and weighs about five tons. The speed is about 4,000 revolutions per minute, and the air gap is less than 1 millimeter At the normal output of 110 kilowatts, the aerial current is approximately 135 amperes, but it is claimed that the machine is capable of generating as much as 200 kilowatts.

The receiving apparatus is ingenious in that the tone heard in the receiver is the difference tone between the transmitted frequency of 40,000 cycles, and a mechanically produced frequency of about 39,500 cycles, thus giving a 500-cycle tone in the receiver It is claimed that this system eliminates largely the interference from both static electricity and other stations

The Nitrogen-filled Lamp—In these days of such rapid advance in the art as well as the science of illumination, it would be a fearless prophet who would attempt to predict the future of the new nitrogen filled tungsten lamp It is not difficult, however to point out a few types of service for which the new lamp is especially adapted.

Since it is in only comparatively large sizes that we find the remarkably low specific consumption of 0 5 watt per candle-power we shall look for the first commercial development in connection with exterior lighting and the lighting of large interiors.

The efficiency of the gas-filled lamp increases with the diameter of the filament, thus making the high current lamp the first to be put on the market and we find them used extensively on the standard 6.5 and 7.5 ampere lighting circuits. With even better efficiency, lamps drawing a current of 20 or more amperes might be used on alternating current series circuits with a compensator or current transformer for each lamp

Another important class of work for which the new lamp seems peculiarly adapted is in projection lanterns small search lights and in all places where a steady light of high intrinsic brilliancy is desirable

Although the gas-filled lamp may replace the present type of enclosed carbon arc it is a question for the future to decide whether it can compete with the high efficiency arcs such as the magnetite and the quartz mercury lamps While the efficiency of the new mazda is of the same order as that of these arcs, the cost of maintenance is a factor which may be of greater importance than the actual specific consumption of the lamp

It is probable then, that the extent to which the nitrogen filled lamp will be used is largely a matter to be decided by the cost of manufacture and cost of maintenance of several of the better lamps of to-day, and the adaptability of each to special types of service

The Split Phase Motor.—A recent development in electric traction which is important from a technical point of view is the so-called "Split Phase Motor." This motor is not a new traction motor but a motor used as an intermediate step between the line and the traction motors and its function is to change single phase current into polyphase current. It is not a motor generator set but a straight induction motor run as a single phase motor with additional windings so interconnected that polyphase current can be supplied to the traction motors. This motor is kept running continuously, and power supplied to polyphase motors only when the car is operated.

The polyphase induction motor because of its simplicity, [illegible] and the possibility of regeneration of power [illegible] ideal characteristics for heavy [illegible] traction. The chief disadvantage is the complicated [illegible] system [illegible] and the trouble in [illegible] current. The use of the split phase motor [illegible] the use of polyphase motors with single [illegible].

[illegible] of the Norfolk and Western R. R. over the [illegible] Division in Virginia. [illegible] is primarily a freight hauling road, traffic [illegible] This motor is ideally adapted to these conditions and in this case proved cheaper to install

The technical journals term this system The Single Phase-Polyphase System

MECHANICAL ENGINEERING

First Stumpf Una-Flow Engine Built in America—The development of the una flow engine promises much for the future of the steam prime mover It is therefore of interest to note the introduction of this engine into America The Ames Iron Works have recently constructed the first una flow engine to be made in this country with the approval of Prof Stumpf

As is commonly known the una flow engine has effected an increased economy because of reduced cylinder condensation losses This is due to the fact that the steam is exhausted at the other end of the stroke from that at which admission occurs Hence the steam in entering is not passed over the cooler end of the cylinder lowered, at the end of the stroke to the temperature of the low pressure steam By eliminating the loss between cylinders, of a compound or triple expansion engine the same power may be developed with a una flow engine having cylinder dimensions materially less than those of the low pressure cylinder of a multiple expansion engine The Stumpf engine built by the Ames Company shows a reduction of 20 per cent in this respect.

The results of tests on this engine recently published show very significant results. The engine is rated at 100 kilowatts, its dimensions are 15x16 inches and its speed is 250 revolutions per minute The best economies are 12 5 pounds of steam per indicated horse-power hour condensing and 16 8 pounds non-condensing (superheated steam in both cases) These economies are indeed remarkable for an engine of such small capacity, but the most significant feature of the performance lies in the flatness of the water rate curves In varying the load from almost zero to 150 per cent of rating the greatest variation is about 2.5 pounds per indicated horse-power hour When the water rate curves of the best multiple expansion engines are considered, these results appear to be almost revolutionary

Extension of the Uses of Surface Combustion—We first heard of surface combustion practically applied, in the surface combustion boiler of Prof Bone of England More recently, however the principle has been extended with marked success into the field of domestic heating and the heating of buildings

Briefly, surface or flameless combustion is effected by premixing the air and gas and impinging a jet of the mixture on a porous surface, in which the combustion takes place When gas is burned in flame combustion the gas jet depends for its air of combustion on the dissipation of gas at the edges of the jet The combustion wave or impulse therefore travels through the gas at a relatively slow rate and the combustion is both slow and often imperfect In the case of a mixture of air and gas the combustion wave travels through the mixture at an explosive rate and combustion is practically perfect This is what occurs in surface combustion the process taking place in the pores of the surface The result is merely a glowing of the surface, entirely without flame It is of course necessary to preheat the surface in order to start the surface combustion This may be accomplished by burning the gas in a flame impinged upon the surface before premixing begins It is further evident that the speed of the jet of mixture must exceed that at which the explosive impulse travels through the mixture in order to prevent back-fire.

One of the most notable applications of surface combustion is in the heating of rooms Ordinary heating systems depend almost entirely on convection for the dissemination of heat through a room It may be seen, however, that the rapid combustion in the pores of the surface by this new method, creates heat in the radiant form This is a much more efficient means of heat transfer for practically all heating purposes The surface combustion room heaters have the appearance of a small plate which is generally located in the ceiling This form of heater seems to be meeting with marked success The surface combustion principle is also being used now in stoves and for other domestic purposes.

The Humphrey Pump—No discussion of recent engineering developments would be complete without mention of the Humphrey pump, being as it is so radical a step in pump design. This subject, however, has received so much attention in the technical press that the reader is referred to this source of information.

CIVIL ENGINEERING

Bridges.—In the field of bridge engineering undoubtedly the most significant development is the use of alloy steel, particularly nickel steel in bridge structures The advance of bridge design has called for steel of much greater strength than that of any carbon steel. The demand has resulted in extensive research of the properties of all y steel with the result that nickel steel has been adopted quite extensively for this class of work The most notable examples of the use of this steel are three large bridges now building viz the Hell Gate bridge in New York the new Quebec bridge and the bridge at Memphis Tenn which spans the Mississippi River The last named bridge is being built alongside of the old bridge at that point so that an exceptional opportunity is afforded to contrast an old time structure with the most recent design

Railroad Engineering—The most important recent developments in railroad engineering may for convenience be grouped under construction operation and management

The construction work in this country has been largely in the reduction of gradients and curvature and the improvement of terminals the former to reduce the cost of transportation and the latter to increase its convenience The former has been largely an economic problem the increased cost of transportation over the sharp curves and steep gradients for the heavy traffic becoming greater than the interest and maintenance for the new construction

The latter has involved a large amount of expensive grade separation work in reaching the centers of population to reduce delays due to street travel and to increase safety for both the street and railroad travel To quite an extent, this has been forced upon the railroads by public opinion but it has usually been found profitable in the development of suburban business and in saving of time and increased safety but in the construction of some of the recent large passenger stations the economic limit has been passed even after allowing for the advertising value in attracting competitive traffic

In operation on the low grade lines with heavy traffic the strength and safety of track limit the speed and weight of train For dense traffic the unit cost decreases with increasing weight which makes a constant demand for stronger track A few years ago the defective rail was the limiting factor but thanks to the work of the rail experts and the keen interest of both the rail makers and the rail users the open hearth steel rail of to-day is giving excellent service The tie plate is rapidly coming into use for both safety and economy while the screw spike is being tried extensively It is felt by many that the ballast and sub-grade will also require strengthening for any further material increase in wheel loads or in loads per foot of track

The safety first movement is having its effect on those responsible for the operation of trains as well as upon those responsible for roadbed and equipment.

The thorough investigation of earnings which has been made in connection with the request for an advance in freight rates is having an excellent effect in bringing about a study of the economics of operation which should result in mutual benefit to the railroads and the public while the physical valuation by the Interstate Commerce Commission may not prove to be such a calamity as at first predicted

X-Ray Diffraction Patterns

A CORRESPONDENT of *Science* Mr W W Strong of the Carnegie Institute says

The diffraction patterns discovered by Friedrich Knipping and Laue have been shown to be due to the arrangement of the atoms of crystals into planes These patterns are used to indicate the spatial distribution of atoms in crystals

An experiment illustrating these patterns can be very easily shown to an audience by permitting a beam of light to enter a dark room and fall upon the face of a diamond such as used in rings The diamond is held a few inches from the hole through which the beam of light enters and upon this screen is thrown a large number of bright spots very closely resembling the X ray patterns By moving the diamond to and fro from the screen or by rotating it the form of the pattern can be altered The portions of rays that enter the diamond and are reflected from the rear surfaces may show the spectral colors.

This experiment can be demonstrated to a class very easily and should be of some use in explaining crystalline structure

A Shortage of Wood-pulp Threatened

A REPORT by the Forest Service of the U S Department of Agriculture states that because of the war English manufacturers and consumers of wood pulp have been caused considerable uneasiness. Production is at a standstill in the countries at war and in Norway and Sweden, principal sources of supply mills have been greatly hampered because of a lack of coal and chemicals. England has practically no domestic sources of pulp.

An X-Ray Inspection of a Steel Casting*

Experiments on a Method for Discovering Hidden Defects in Metal

By Dr. Wheeler P. Davey, Research Laboratory, General Electric Company

It has always been true that as soon as a new tool is perfected unsuspected applications of that tool rapidly develop. This has been especially true in the case of the Coolidge X-ray tube. It is planned to publish from time to time results of such special applications as may come within our experience. Possibly the question of observing the pipe in a steel ingot by the use of the X-ray, thereby being able to determine just where the ingot should be cropped, may seem still somewhat removed, at least in so far as commercial applications are concerned. There is no inherent impossibility in the process, however. The case now being described is a long step in this direction. It is the object of this article to describe in detail what has already been done in the way of an X-ray examination of a certain steel casting of which suspicion had been aroused as to its homogeneity when in the machine shop.

Fig. 2.—Radiograph of steel casting

Some of the imperfections have been chiseled out of the steel. The chisel marks and some remaining imperfections show plainly

The original casting was two and one half inches thick and weighed about a ton. When received at the Schenectady Works of the General Electric Company it had been machined down to approximately the desired shape and thickness. The amount still to be taken from the faces was not more than one eighth inch, and in some places was only one sixteenth inch, but when this was removed it was found that some small imperfections had been cut into. These extended over an area about five inches long and one and one half inches wide.

The mechanical department at once chiseled away a part of the surface at this point, and then sent the casting to the Research Laboratory to determine if by means of an X-ray examination it might be possible to reveal still other hidden blow holes or imperfections.

A Coolidge tube especially made for use on high voltages was set up in front of that part of the casting where the imperfections had been found. An 8 by 10-inch Seed X-ray plate was mounted immediately behind the casting and the plate was backed by a large sheet of lead. The distance from the source of X-ray to the plate was 20 inches. The tube was excited by an induction coil with a mercury turbine interrupter. The current through the tube was 1.25 milliamperes and the potential across the terminals of the tube corresponded to that sufficient to break down a 15-inch spark gap between needle points. The X-ray plate was exposed two minutes. At the place where the radiograph was taken the finished casting was about nine sixteenths of an inch thick. The radiograph obtained is shown in Fig. 2. The casting was then moved eight inches and another radiograph made. In this way a number of exploratory radiographs were taken through different points of the casting.

All the radiographs thus taken showed plainly the tool marks on the surface of the casting. *All but one* showed peculiar markings which were of such shape as to strongly suggest that they were indeed the pictures of holes in the interior. In the words of the surgeon it was decided to confirm the diagnosis by making an exploratory incision. A circular piece, one inch in diameter, was punched from the casting at a point where one of the radiographs indicated that a blow hole should be found. (Location of sample shown by circle on Fig. 3.) Figs. 4 and 5 show that the surfaces of the casting were entirely free from blow holes at the point where the button was removed. Figs. 6 and 7 show the ends of the hole in the button.

This has proved then that with the proper X-ray exposure blow holes or cavities may be disclosed in apparently solid metal of considerable thickness. A careful comparison of the X-ray photographs and the button photographs leads to the conclusion that very small air inclusions are made visible, and the fact that the tool marks are plainly visible on the X-ray plate confirms this fact.

Such studies point to the desirability of great care in metal casting where imperfections ordinarily invisible are of great danger, and where X-ray analysis or some other method is not used to check them.

Irrigation With Fresh Water from the Sea*

By E. J. Moynihan

There are many parts of the earth's land surface quite near the sea, and at a very low elevation, where little rain falls, which are actually or nearly desert. A great part of the Sahara, certain parts of Australia, and portions of South Africa, fall into this category. These, and many other parts of the world at a greater elevation now useless for lack of natural water, and so placed that no ordinary irrigation scheme is applicable, could be transformed into fertile provinces, like the irrigated deserts of the Western States of America, if a cheap supply of fresh water for irrigation purposes could be brought to them.

It is not necessary to prove that the cost of fairly long canals to bring the water to the spots to be irrigated is not prohibitive. Such canals for gravitation systems of irrigation, already exist, as paying concerns in large numbers all over the world. In the case of water brought from a lower level it is necessary to show that in many cases the cost of pumping is not prohibitive either.

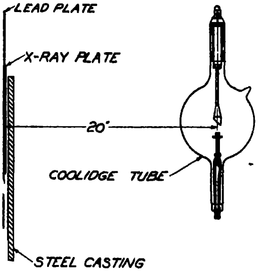

Fig. 1.—Diagram of set up for taking pictures of steel casting. Drawn to one eighth scale.

In dealing with the cost of pumping I shall take the head of water produced by the pumps to be 50 per cent more than the actual height to which the water is to be raised. I shall allow roughly for an efficiency of 75 per cent in the pumping plant, in addition to the absorption of one-third of the energy delivered to the water by the pumps in friction in the water channels. Assuming an annual requirement of 2 000 tons of water per acre (which is approximately equal to a 20-inch rainfall) 100 feet of effective lift calls for the expenditure at the pumps of

$$\frac{2 \times 2000 \times 2240 \times 100}{33000 \times 60 \times 24 \times 365}$$

* Read before the South African Institute of Engineers.

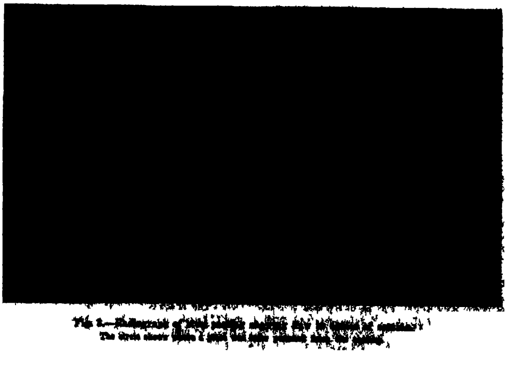

Fig. 3.—Radiograph [illegible]
The circle shows [illegible]

of approximately one-twentieth of a horse-power year. On a large scale and in favorable situations electric power can be produced from coal for less than £5 per horse-power year. The pumping charges for water per acre would therefore be on the above basis, something like 5 shillings per acre, which is by no means prohibitive. Irrigated land, formerly almost worthless has recently changed hands in South Africa at about £200 per acre. The interest on this value at 5 per cent would pay forty times the annual charge which I have calculated.

This annual charge might in the future itself easily be reduced to a fifth of the figure I have taken. If this is done irrigation at an elevation of 5 000 feet with water pumped from sea level would be practicable. With modern improvements in gas making and the attention that is being paid to the recovery of the waste products in the gas-making process it is quite conceivable that the power-gas might become the waste-product. The present type of gas engines are capable of very great advances in thermal economy. It would require no very great improvement of this kind to bring down the fuel consumption to ¾ pound of carbon or coke per electric brake horse-power per hour or less than 3 long tons per year. At 5 shillings

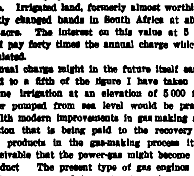

Fig. 4.—Photograph of top surface of casting at place where piece was punched out

Note that no imperfections are visible. The U is a punch mark to identify top of piece cut out

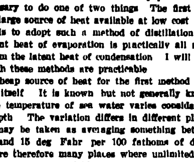

Fig. 5.—Photograph of bottom surface of casting at place where piece was cut out

Note that no imperfections are visible at the surface

Fig. 6.—Photograph of one edge of button which was cut from the casting (see Fig. 3), showing position of hole. Button was 9/16-inch thick.

Fig. 7.—Photograph of edge of button opposite to that shown in Fig. 6

a ton the cost of fuel for power would be reduced to 15 shillings per annum per horse-power or about one-sixth of the £5 per horse-power year that I have taken above. This reduced figure takes no account of by-products on the one hand or capital charges on the other. These two items might easily balance one another.

To bring great supplies of water from a distance implies the use of very large channels, which are very expensive if made artificially. In the case of supplies brought from the sea, where the water is to be raised from a lower to a higher level these channels are there already in the existing streams. All that is necessary is to dam them cheaply so as to give moderate lifts of, say, 4 or 5 feet, at the narrowest parts of their courses. The flood water of the rivers could then be partly stored in up-country irrigation dams, and partly allowed to go out to sea to prevent "silting-up." The pumping stations would be advised, by telegraph or telephone in advance of the arrival of the floods, or automatically controlled so that they would do no unnecessary work.

The streams, treated in this way, would also serve for the cheap transport of fuel and other material, including such parts of the crops produced as were in no need of hurried travel. At even two miles an hour, goods would only take about four days to travel 200 miles, which is not so very much slower than the actual rate of travel for coarse goods over similar distances, when truck demurrage is taken into account. By adopting a system with automatic loading and discharging the expense of bringing coal to the pumping stations would be reduced to a very low figure. At the [illegible] proposed 1 horse-power hour will do about [illegible] against a 2-mile current.

[illegible] by the [illegible] method of burning salt, [illegible] water so cheaply as to make the scheme practicable.

These are only possible solutions of the problem. Chemical means I shall reject for the purpose of this paper because in the first place I don't know enough chemistry and in the second place it is only necessary to show the feasibility of physical methods.

A simple physical method of purifying salt water is to distill it. To make this commercially practicable it is necessary to do one of two things. The first is to have a large source of heat available at low cost. The second is to adopt such a method of distillation that the latent heat of evaporation is practically all recovered from the latent heat of condensation. I will show that both these methods are practicable.

The cheap source of heat for the first method is in the sea itself. It is known but not generally known that the temperature of sea water varies considerably with depth. The variation differs in different places but it may be taken as averaging something between 4 deg. and 15 deg. Fahr. per 100 fathoms of depth. There are therefore many places where unlimited supplies of water are available at temperatures differing by say 5 deg. Fahr. the warmer water being on the surface and the colder water at a depth of from 30 to 60 fathoms. These spots should be prospected for. In Summer when irrigation water is most needed the temperature gradient is very much steeper than the above figures show especially in hot latitudes. In the English Channel at Station E_2 in August 1904 the gradient was about 8 degrees for 8 fathoms. In the Central Pacific a difference of 30 degrees has been observed for 100 fathoms. In the Red Sea the conditions are probably similar to those of the Pacific. It is therefore probable that for those months in the year in which water is most needed there are suitable places near shore where a temperature difference of 5 degrees exists in very moderate depths of water. It is hardly necessary to tell engineers that under these conditions it is easy to evaporate the water at the higher and to condense it at the lower temperature.

As we have to deal with very small differences of pressure the condenser plates may be made of very thin metal as thin or thinner than an ordinary sheet of galvanized iron.

With suitable circulating methods each square foot of condenser surface would produce about 2 pounds of condensed water per hour for a temperature difference of 4 deg. Fahr. or roughly 8 tons per year. For the 2 000 tons assumed as the requirement per acre 250 square feet of condenser surface at 6d. a foot would mean a capital expenditure for condenser surface of £6 5s. per acre to be irrigated.

The calculation of the surface required is based on the assumption that about 500 heat units are transmitted per square foot of condenser surface per hour per Fahr. degree of temperature difference. With proper design and circulating arrangements it is possible to increase this figure to more than 3,800 or more than seven times as much. (See foot-note p. 593 of "The Steam Engine," by Perry.) This would reduce the capital cost for *condensing surface* to less than £1 per acre to be irrigated.

With the use of rivers as main irrigation channels as suggested, there would be no need to take channel evaporation into account, as the natural flow of the rivers already accounts for this, and the back percolation of the water from the irrigated land to the river channels would also offset the evaporation.

An evaporation plant based on the above facts and figures would necessarily deal with very large quantities of water in order to be a payable proposition. The intakes for the circulating water would have to deal with such quantities of water as pass out to sea by small rivers. But as their cross-section would be comparable with that of rivers, so the friction head required for circulating purposes would also be of the same order or something like a head of 1 inch for 100 feet of conduit. The stresses on the conduit would also be as nearly negligible as the difference in pressure between the outside and inside of the pipe. The material of which the conduit was made could therefore be quite inexpensive. The condenser plates could be immersed in the water at the top of the conduit itself. Assuming that the condensation water only took up one heat unit per pound of water condensed and that the pumping head required would be as much as 3 inches the work done on the condensation water by the turbo-pumps would be equivalent to lifting the condensed water 250 feet. This I have already shown, by implication not to be financially impracticable. The work to be done at the distilling plant on the condensed water is still less so being only a small fraction of the work done on the condensation water. The total pumping work to be done at the evaporator calls for an expenditure of from 6 shillings 3 pence to 25 shillings for power per acre irrigated with power costing from 50 shillings to £10 per horse-power year.

The second method of distilling the water consists of increasing the pressure and therefore raising the temperature of the distilled vapor or the water to be distilled by mechanical means such as a compressor turbine and condensing the vapor in a surface condenser the condensation water being the same water that is being evaporated. In this way the whole of the latent heat of condensation is returned to the water which is being condensed. The net amount of heat supplied mechanically depends on the difference of temperature between the condensed water and evaporated water.

Taking this as 4 degrees the net amount of heat is substantially 4 heat units per pound, or about 9,000 heat units per ton of water evaporated. With an efficiency of 25 per cent over all in the gas-engines and mechanical arrangements less than 3 pounds of carbon would therefore be consumed to distill 1 long ton of water. With a requirement of 2 000 tons of water per acre irrigated the carbon consumed annually per acre is slightly less than 2.7 tons costing at 5 shillings to 20 shillings a ton from about 13 shillings 6 pence to 54 shillings per annum for fuel. The fuel bill could be proportionately reduced by reducing the temperature difference.

With this second method of distillation no works would be necessary in the sea itself. The apparatus would all be inshore with a canal leading water to it from the sea at one end and taking water away at the other. One great advantage of this second method of distillation is that much less water has to be handled than in the first. Practically all the water requiring handling is that required for distillation and irrigation. The latent heat withdrawn from the water distilled being practically all returned to it in the act of condensation the natural tidal circulation is sufficient to renew the main body of water dealt with rapidly enough to carry the increasingly saline water out to sea. Taking capital into account this second method is probably cheaper than the first method of utilizing the heat in the sea water itself.

The second method has other conveniences. It can be run profitably on a much smaller scale than the first, it calls for less capital expense and it can be used to produce water all the year round under almost uniform conditions. This would allow of deeply ploughed ground being cultivated on a system combining the advantages of dry farming and irrigation in such a way that the water could be used evenly as it was produced all the year round.

Impact from Flat Wheels

Tests have been made at the Purdue University to determine the effect of impact resulting from flat wheels and the investigations covered spots of varying sizes and wheels running at different speeds and with varying loads. It has been found that an imperfect wheel with a 3 inch flat spot strikes the track with an impact of 104 000 pounds when the car is going 16 miles per hour and is carrying a load of 20 000 pounds. It was also found that under similar conditions a flat spot only 1½ inches in length produced a blow of 20 000 pounds, and the impact for spots 2 inches long was 25 000 pounds. A standard freight car was mounted in the test laboratory and special apparatus, including an instrument which recorded photographically the magnitude of the blows, was employed to collect test data.

The European War and Potash Supplies

A Consideration of the Possible Sources of Material for Home Manufacture

By Thomas J. Keenan

In the closing years of the eighteenth century, when the French revolution was at its height, conditions in France as regards the supply of soda bore a curious resemblance to the situation in America to-day as regards our supply of potash, the political conditions being of course very different. France was wholly dependent on Spain for barilla, a variety of soda ash made by burning saltwort and sea plants, and also imported large quantities of Spanish potash. Commercial intercourse between France and Spain had ceased on the outbreak of the revolutionary war, and all the potash which France produced was required for the manufacture of saltpeter and gunpowder in this emergency. The National Convention made an appeal to the chemists of France to devise a process in which common salt might be made available as a source of soda. The call was heard by an obscure chemist, Nicolas Leblanc, who came forward with a process for the conversion of sodium chloride into sodium carbonate that has made his name an immortal one in the annals of chemistry. The Leblanc process has never been entirely superseded; indeed new plants are constantly being established, despite the superior advantages of the Solvay process for most purposes in the production of carbonates of soda.

Now that the supply of German potash for agriculture and industrial uses has been cut off completely by the European war, a situation has been created in the United States not very dissimilar to that which prevailed in France in revolutionary days, and fame and fortune await the American inventive genius who will arise to solve the great problem of producing potash economically and abundantly from the potash rocks, brines, and bitterns native to the United States. Leblanc achieved fame, but died a pauper.

The primitive product of the lixiviation of wood ashes, known for centuries as potash, is not an article with which twentieth century chemists can lay claim to much, if any, familiarity. The article supplied in sticks—potassium hydroxide—is what is recognized as potash in the laboratory. Our forefathers knew the wood ash product better, and there are doubtless many now living who can recall early days on the farm when potash was collected for domestic soapmaking by the simple process of leaching the ashes of burnt hickory or other logs. A century or more ago, however, when vast natural forests existed and the value of lumber was little more than that of the labor of felling it, the manufacture of potash from wood ashes was an industry of considerable importance.

Although potash is still manufactured from the ashes of wood in the forests of Northern Michigan and in portions of the provinces of Canada, the quantity so produced is negligible and finds use in a local way only.

The German potash industry dates from 1861, when the first factory for refining crude potash was established by Prof. Adolph Frank at Stassfurt. Stassfurt has been known for its salt industry for more than 500 years, the records of the town showing that a guild of saltmakers had worked the salt beds of the district as far back as the thirteenth century. At the time the deposits were taken over by the Prussian government in 1798, and some time later worked on a commercial scale, the potash was treated as a useless by-product, but the researches of Justus von Liebig in agricultural chemistry in 1860, having established the fact that plants depend for their nutrition on the existence in the soil of nitrogen, potassium, and phosphorus in certain definite proportions, and that it was useless to feed a plant on nitrogen and phosphorus unless the right proportion of potash was also supplied, intensive inventive work was begun to discover sources of soluble potash. Liebig's discovery had the effect of directing efforts to the extraction of the potash from the salt beds at Stassfurt as a main product, and this was successfully accomplished after the establishment of the factory by Frank. The potash salts were henceforth worked exclusively and salt became the by-product. In this way was developed the great German potash industry on which the whole world is now dependent for its supply of soluble potash for use in agriculture and the industries.

At the outbreak of the war Germany was exporting annually to the United States 1,115,505 tons of potash for use as fertilizer and in the manufacture of chemicals, this representing about one tenth of the annual output of the German mines, which exceeds eleven million tons.

The German potash minerals are now mined over a large extent of country, and it is no longer accurate to speak of them as "Stassfurt deposits." Reaching to a depth, from the top of the upper to the bottom of the lowest stratum, of some 5,000 feet, the beds underlie a tract of country extending from Stassfurt to Thuringia on the south, to Hanover on the west and to Mecklenburg on the north; while deposits were discovered and mines opened a few years ago in Alsace near Mülhausen, where the German troops are now repelling a French invasion.

Notwithstanding the apparently inexhaustible extent of the German salt deposits they are really insignificant compared with the abundance and variety of potash rocks (feldspar, etc.), which occur everywhere in the earth's crust. It is their solubility in water and consequent ready amenability to chemical treatment which gives the German salts their great industrial importance, and makes it appear altogether impossible for any other known sources of potash-containing minerals to compete successfully with them. Deposits similar to the German have lately been discovered in Spain, and, if they prove to be as soluble and as accessible, competition may be expected, but adequate reports on this source of supply are not available at the present time.

Although German potash is not contraband of war and none of the nations at war objects to its movement in neutral ships, it has not been possible to move it from the mines and storehouses to the coast on account of the monopolization of railroad and river traffic by the army and navy, so that not a ton of potash has been shipped to the United States since hostilities started last August.

Potash has a wide and necessitous use in many fields of industry besides pharmacy—in agriculture, glass manufacture, and soapmaking, to mention some of the more important. The serious problem now confronting the country is to find substances that will yield water-soluble salts of potash in sufficient abundance to provide relief from the deprivation of the German supply and at the same time put our farmers and chemists in a position of economic independence for the future.

The mineral sources of potash include the salts and brines found in the lake basins of the arid West, notably in Utah, Nevada and California; the mineral alunite, a double sulphate of potassium and aluminium, lately found near Marysvale in Utah; and certain natural silicates or potash-bearing rocks, as feldspar, etc. Although a great deal has been published concerning potash mines and deposits in Nevada, no one out there appears to have ever heard of their being worked.

Kelp, or seaweed, contains a notable quantity of potash in combination with chlorine, and the stretch of giant algæ groves on the California coast are rich in potassium chloride, being estimated to contain up to 30 per cent of potash in the ash, and in some cases up to 2 per cent of iodine, which substance it is considered would largely pay the cost of production of the potash.

The most promising source among the lake beds of the West is Searles Lake in San Bernardino County, California. Borings show that the deposits in this lake bed consist of a mass of salts about 70 feet thick. These salts are made up of sodium chloride. The structure of the mass reveals a coarsely crystalline and honeycombed form, the spaces being filled with brine. Below a salt bed extending down for a distance of 23 feet, a brine is found which analyses about 4½ per cent of potassium chloride. A plant has been recently started for the extraction of the potash by a spraying and evaporating process. This is expected to have an output of 120 tons a day when working at full capacity, but the entire deposit, according to Government estimates, amounts to only 600,000 tons—less than a year's supply!

A promising source of potash as a by-product is the Portland cement industry. By replacing the clay ordinarily used in cement manufacture with finely ground orthoclase or potash feldspar, it would be possible to obtain as a by-product a quantity of potash equal to about one million tons a year. Any granite rock, gneiss, feldspar, or phonolite would do as a substitute for clay in this process. All that is necessary would be to grind the rock, mix it with limestone and heat the mass to a higher temperature than is ordinarily done in cement work, or say, 1,400 deg. Cent. The potassium is driven out by the lime, and converted into a carbonate, more or less mixed with impurities from the cement, but easily soluble and readily refined. The product obtained by this process is said to yield 65 per cent of [illegible]

Among the minor sources of potash that might be worked for industrial purposes, for the manufacture of pharmaceutical salts, etc., the waste liquors from the manufacture of beet sugar are worthy of note. Some 15,000 tons of potassium salts are obtained annually in Germany from this source alone, and as Prof. Lloyd has pointed out, the waste liquors of the French beet sugar industry were at one time a fairly good source of potash, large quantities of a crude carbonate obtained in this way being at one time imported by American chemical manufacturers. On the assumption that the molasses of the American beet sugar industry contain the same proportion of potassium that is present in the German and French sugar beets, there would seem to be an opportunity in this country for the exploitation of potash manufacture as a by-product of this industry. Beet molasses, or the residues left after the extraction of the sugar, contain the total potash salts of the root. This material is either charred directly, yielding *schlempkohle*, or it is desaccharised, or fermented and the final liquors (*vinasse* or *schlempe*) from these processes are evaporated to dryness and the residue calcined to a black porous mass which, after appropriate treatments, yields a product containing about 85 per cent K_2CO_3 and 8 per cent Na_2CO_3.

It has also been suggested that the waste liquors of the sugar industry in the South might be utilized as a source of potash, but it is not known how large a yield might be expected, or if the process of extraction could be operated so as to prove a commercial success.

An interesting source of potash is sheep's wool. In the internal economy of the sheep, the potash ingested by the animal as constituents of the roots, herbs, and grasses on which it feeds, is excreted mostly as sweat, one third of the weight of raw merino wool being said to consist of potassium compounds. No attempt has been made in American sheep-raising districts to save this potash, though in France as much as 1,125 tons of wool potash are produced annually by several wool-washing plants. Wool yields about 180 grammes to 190 grammes of potassium carbonate per kilo of combed wool, or from 18 to 19 per cent of potash. The raw wool is washed with cold water, whereby the potash soaps, with some of the neutral fat and cholestrol, are extracted. The solution is evaporated to dryness and calcined, giving a residue containing about 85 per cent K_2CO_3, the remainder being Na_2CO_3, together with K_2SO_4 and KCl.

Among plants the ashes of which are particularly rich in potash, sunflowers, tobacco, and fumitory may be mentioned. Potassium carbonate once went by the name of salt of wormwood, the ashes of this plant being largely used at one time for its production, just as it was called salt of tartar from the fact that cream of tartar was once employed as the source of a pure article. In a table published in Crooke's translation of Wagner's "Chemical Technology," the following figures are given of ash and potash yields of 1,000 parts of the woods named:

Wood.	Ash.	Potash.
Pine	3.40	0.45
Beech	5.80	1.27
Ash	12.20	0.74
Oak	13.50	1.50
Elm	25.50	3.90
Willow	28.00	2.85
Vine	34.0	5.50
Dried ferns	36.4	4.25
Wormwood	97.4	73.00
Fumitory	219.0	79.90

Familiarity with the extent of the available supply of potash in Germany, and the cost of production there, leads to the conclusion that it would be a hopeless undertaking to attempt competition with our present resources. If 150 of the mines now worked in Germany were to cease producing potash, enough would be available in the forty remaining mines to supply the world's requirements. It is said that the best grade of potash sold could be mined, refined and delivered at the port of New York for about [illegible] a ton and still clear a profit, if the authorities in control of the mines were compelled to do so by stress of competition. The price paid in cargo lots by American [illegible] for this grade of potash is from [illegible] to [illegible] a ton. [illegible] readily explains why the Kali Syndicate [illegible] expend a million dollars a year for [illegible], one fourth of which is spent in propaganda work in the United States.

Discoveries About Bacteria*

A Simple Description of What They Are and What They Do

By Sir Ray Lankester, K.C.B., F.R.S.

THE London newspapers are afflicted by a dangerous eagerness to provide their readers with short articles announcing "something new." I am sorry to say they are sometimes not very particular as to whether their announcements, when relating to matters of physical science, natural history and medicine, are true. It would take up much space were I to give a complete list of the items of rubbish which are now being daily foisted on the newspaper reader by ignorant writers, who are encouraged by some newspaper proprietors to write "smartly" and "informingly" about scientific and medical subjects of which these writers are ignorant and concerning which they make outrageous blunders.

I will here notice only one of these recent misleading announcements. It relates to a subject which, when properly dealt with, may be of great interest but can easily be made a meaningless absurdity. A paper communicated to the Academy of Sciences of Paris by Dr. Roux, the director of the Pasteur Institute was written by Madame Victor Henri, and describes some observations made by her and M. Victor Henri in the laboratory of Dr. Borrel in the Pasteur Institute, with regard to the change of character caused by the action of ultra violet rays of light acting on the bacterium known as "Bacillus anthracis," which is the minute microscopic "germ" or infective parasite causing the deadly disease known as "splenic fever," "anthrax," or "charbon" in cattle and sheep and as "malignant pustule" in man. This little paper is an interesting contribution to the subject. But somehow or other its title attracted the attention of the Paris news purveyor and accordingly we had it announced by telegrams to London papers as a wonderful revolutionary epoch-making discovery which must at once be proclaimed to the British citizen at his breakfast table. He was naturally inclined to ask, "Who on earth cares if the ultra-something rays do act somehow or other on bacillus what's its name?" Since most people must be as no doubt was desired mystified by the announcement and some perhaps soothed by its phraseology as by the blessed word "Mesopotamia" (in fact as we may say "mesopotamified") I will endeavor to state in plain terms what it really amounts to.

The name bacterium—meaning a short rod—was applied a hundred years ago to a common rodlike microscopic form (often only one twenty-thousandth of an inch long and a third of its length in breadth) occurring by millions in putrefying vegetable and animal refuse, and well known to all who used high powers of the microscope to explore natural waters such as ponds and sea pools. They were first seen and described 230 years ago by the Dutchman Leeuwenhoek who found them in millions in the human mouth. Each rod multiplies by dividing as it increases in length into two. From a single rod many millions are thus produced in the course of 24 hours. The Austrian botanist Nägeli, about sixty years ago gave them the name "Schizophyta" or "splitting plants" on account of this mode of rapid multiplication. According to the nature and abundance of the material (animal and vegetable refuse) in which they are growing they assume different simple forms. Some grow into long hair-like filaments before splitting into small rod-like bits; others break up into tiny spheres, called "cocci" or "micrococci," others take on a spiral, or corkscrew form, and are called "spirilla," and break up into little curved bits called "commas," or "vibrios," while others, rod-shaped like the original "bacteria," but a little longer in proportion to breadth, are known as "bacillus." Often they are motile, being provided with one or more excessively delicate vibrating threads of protoplasm, which keep them in constant and rapid movement. The same kinds will, under certain conditions, cease to move, and throw out as they grow and multiply an abundant jelly, in which they are embedded. Most of them can withstand the effects of the drying up of the moist matter in which they grow, and are blown about as dust, apparently dead, but revive into active life when they fall into liquid, or on to a moist surface. Consequently, they are ubiquitous, and we know of hundreds of kinds of them occurring in almost every imaginable position where their proper nourishment, namely, the moist substance of living or dead animals or plants, can be found.

Not only can they resist the temporary suspension of their life by dryness, but some are not killed by exposure to the heat of boiling water for some minutes, though most are killed by heating to that or a somewhat lower temperature. Great cold even that of liquid air does not kill them but suspends their life so that they recover with increase of temperature. Strong sunlight kills them, some kinds more quickly than others. They are chemically altered and soon killed by the invisible ultra violet rays which accompany the light rays which act upon our eyes. Those rays are given out by the sun and by many other incandescent or light-producing bodies, such as gases and the vapors of metals heated in the electric arc of electric lamps. But of course these rays do not in natural conditions fall on to the "bacteria" which are concealed beneath the surface of opaque masses of refuse in mud and inside living animals and plants.

The bacteria are not only excessively minute but the simplest of living things in visible structure. They are just rods or granules of living protoplasm with a dense surface and a granule or two or a liquid-holding space within. They do not possess the peculiar active central kernel or nucleus which is characteristic of the protoplasmic cell-units of animals and plants. Nevertheless they have the most prodigious chemical powers and an astounding variety of such power. They do not feed as green plants do by decomposing carbonic acid with the aid of that real marvel "leaf-green" or "chlorophyll"; they do not take carbon from carbonic acid and nitrogen from nitrates. Nor are they limited to the albuminous substances of flesh and of plants for the necessary nitrogen of their food as are all animals. They have very special and varied powers of digestion like those of the molds, yeasts and fungi—the colorless plants. They do not digest their food as animals do by taking bits of it inside them and there chemically operating upon it. Their food does not get into them as does that of animals but they get into it. They set up most remarkable and definite chemical changes in the animal and vegetable refuse in which they multiply, changes which may be compared with those effected in the stomach and intestines of animals where they are called digestion. Gradually chemists are getting to know the nature of some of the digestion-like changes produced by different kinds of bacteria. But their full discovery requires the greatest skill and delicacy of experiment and has yet to be attained. The chemical action exerted by another class of minute vegetable organisms, the yeasts, when they cause fermentation, breaking up the sugar of malt in the brewer's vat into carbonic acid and alcohol is similar to the chemical action of many bacteria. They feed and multiply in the process of chemical fermentation which they cause just as the yeast plant does. Putrefaction with its accompanying foul-smelling gases and destruction of dead animal and vegetable matter is a fermentation caused by bacteria just as the production of alcohol and other bodies from sugar is the fermentation caused by beer yeast.

All the dead bodies and waste excreta of all animals and all plants on the surface of the globe are thus broken up by bacteria. Putrefaction and decay is the result of life, the life of bacteria, and not of death. All bad smells except those made by chemists are made by bacteria. If there were suddenly a destruction of all bacteria the earth's surface would be encumbered by the unchanged bodies of its animals and plants as they died and accumulated. Not merely that but all the carbon and nitrogen would be fixed and "held up" in those dead bodies—for the putrefaction caused by the bacteria is carried on step by step—until those essential elements are returned to the water and the soil of the earth as carbonic acid and nitrates. The green plants must have the carbon and nitrogen of their food in the stable, simple soluble chemical compounds called carbonic acid and nitrates. They cannot feed on the carbon and nitrogen built up into the fat, sugar and albumens of other plants and of animals. If these were not chemically broken down by the bacteria into carbonic acid and nitrates, the green plants would cease to exist, and so would the vegetarian animals which feed on them, and the carnivorous animals which feed on the vegetarians and there would be an end of the whole world of life! The bacteria are the necessary agents for keeping the carbon and nitrogen in circulation, breaking the complex chemical compounds of the bodies of animals and plants down to the simple carbonic acid and nitrates and so returning them in the necessary state of simplicity to the primary builders-up of living substance—the green plants.

Among the important chemical operations of bacteria are the bringing about of oxidation or combination of oxygen with other substances. Different kinds of bacteria separable to some extent by their shape and growth as seen with the microscope but more clearly dangerous by picking them out from their fellows by means of cultivation, sowing them like seed on nourishing films and isolating them and then testing their properties—are responsible for different chemical operations. Some require the presence of free oxygen for their growth, others can do without it (and are called anaerobic), some will flourish in weak acid fluids, others are killed or arrested in growth by acid and require alkaline fluid. Some live in the soil or in the waters of the sea, in rivers or pools, others live on the surface of the bodies of plants and of animals, others inside in the mouth, in the intestines or in the blood and tissues of animals or in the juice of plants. Besides the commoner putrefactions which we recognize by their unpleasant smells there is a kind of bacterium which makes sour milk, that is, converts the sugar of milk into lactic acid, another to which we owe vinegar, converting alcohol into acetic acid, another which gives flavor to cheese by producing butyric acid, and others producing other flavors. Others of great importance are first one which breaks down organic matter already made putrescent by other bacteria into ammonia (familiar through the smell of stables), another which oxidizes ammonia into nitrous acid, and another which oxidizes nitrites into nitrates. These are of essential importance in agriculture and in the change of sewage and natural refuse into food for green plants.

While they are ubiquitous and active and essential in a thousand ways in the world around us, the bacteria have a more personal interest for us when they operate on and in our bodies. They cause fermentations and produce various and often deadly poisons within us. The intestine is full of them, one-third of the solid matter in it being bacteria, and these of many kinds, some harmless, some producing injurious poisons from the undigested food which may be absorbed into the blood. The diseases known as septic poisoning, typhoid fever, cholera, diarrhoea, diphtheria, erysipelas, glanders, anthrax or malignant pustule, pneumonia, influenza, common catarrh, leprosy, tubercle, infantile paralysis and others have within the lifetime of many of us been shown to be due each to a specific kind of bacterium producing specific poisons by its life processes and the chemical fermentations which it sets up in this or that part of the body.

The question has naturally arisen—is each of these enormous and terrible array of bacteria a different kind—that is a different species? Or can one kind become changed and altered in its character and activities by change of conditions so that possibly a harmless non-poisonous kind of bacteria living outside the body, might become altered by parasitic life and change into one that is deadly and poison producing? During the past thirty years experiments and investigations on this question have been constantly carried on. One of the earlier suggestions (due to Büchner) was that the anthrax bacillus is the same organism as that common in hay, the hay bacillus which it much resembles in form and growth. But after careful experiment the supposition has not been confirmed. Experiments on the possibility of altering the form and the chemical activity of bacteria by growing them in novel conditions have been numerous. It was discovered by Pasteur that by growing certain parasitic disease-producing bacteria—outside the body in the presence of oxygen—their virulence as poison producers could be greatly diminished. Recently a paper was communicated to the Royal Society by Mr. Revis showing that the commonest bacterium in the intestine of man known as "bacillus coli" can be completely altered both as to its appearance and chemical activity by cultivating it outside the body in a broth to which a small quantity of an organic chemical compound known as malachite green had been added.

The effect of temperature and of light on particular kinds of bacteria as well as of the presence of various chemical substances in the cultivation have been made the subject of experiment during the past twenty years but has not advanced very far. Hence the experiments made by Madame Victor Henri on the action of the ultra violet rays of a mercurial vapor lamp in modifying the mode and form of growth of the anthrax bacillus and its power of setting up the recognized symptoms of the disease known as anthrax are a welcome contribution to the general inquiry.

The gigantic rock folds in the Canadian Rocky Mountains sculptured by ice

The Origin of the Rocky Mountains*

As Told by Evidence Gathered by the Geological Survey of Canada

By S J Schofield

The elevated and mountainous tract which borders the western portion of North America is made up of a number of parallel mountain systems which trend northwest and southeast and hence parallel in a general way the corresponding Pacific coast line This tract known as the North American Cordillera has a width of four hundred miles in southern British Columbia

In an endeavor to describe the origin of the Rocky Mountains it may be well to precede the discussion by a general analysis of the North American Cordillera in Canada This has been admirably done by Prof R A Daly whose monumental work on the geology of these mountains has just been published The basis for the classification of the Cordillera is the great topographic or geographic breaks which cut it up into distinct mountain systems These geographic breaks are expressed in the form of longitudinal valleys which are remarkable features of the Cordillera and as far as present knowledge goes they coincide with the great structural breaks on which a genetic classification of mountains should be based

On approaching the Cordillera from the east the first range of the Rocky Mountain system rises from the monotonous plains in a long abrupt line of serrated peaks flanked at the base by a low range of foothills This system extends from Montana to the Arctic Ocean in the form of an elongated chain composed of three major segments arranged in echelon in which each successive northern segment is as it were stepped to the west Each segment is composed essentially of a remarkable system of parallel ridges, whose strike corresponds to the general trend of the main range The average width of the Rocky Mountain system in southern British Columbia and Alberta is about sixty miles while at the Liard River it apparently loses its regularity and importance only to again assume the same character farther north In British Columbia and Alberta many peaks exceed 10 000 feet while the average elevation ranges between 8 000 and 9 000 feet.

On the west of the Rocky Mountain system occurs the Great Rocky Mountain Trench a continuous geographic break recognized from Montana as far north as Alaska crossing the international boundary line in the vicinity of Dawson In the southern part of the Cordillera in Canada the Purcell Range—an elliptical shaped mass of rugged mountains occurs west of the Rocky Mountain trench Separating the Purcell system on the east from the Selkirk Range on the west is the Purcell trench in which occur Kootenay River and Kootenay Lake West of the Selkirk Range and separated from it by the Selkirk valley comes the Columbia system The last three systems the Purcell Selkirk and Columbia trend very close to north and south and hence are terminated to the north by the Rocky Mountain system which trending northwest southeast, cuts them off The Columbia Range gradually passes into the Interior Plateaus characterised by low rounded hills and plateau like upland stretches having a mean elevation of 3 800 feet above sea level This is succeeded to the west by the Coast Range which parallels the Pacific coast hence trending in a northwest south east direction The descent into the Pacific is precipitous and many deep fiords mark its contact. The most westerly subdivision of the Cordillera is the Vancouver Range constituted by Vancouver Island and the Queen Charlotte Islands The southern extension of this island festoon is the Olympic Range of Oregon

DISTRIBUTION OF ROCKS

For the purpose of description the Canadian Cordillera can be grouped into two basins of sedimentation a Pacific basin extending from the Columbia system to the Pacific Ocean and an Eastern basin covering the area from the Columbia system to and including part of the Great Plains These basins geologically can be considered as units in a genetic sense

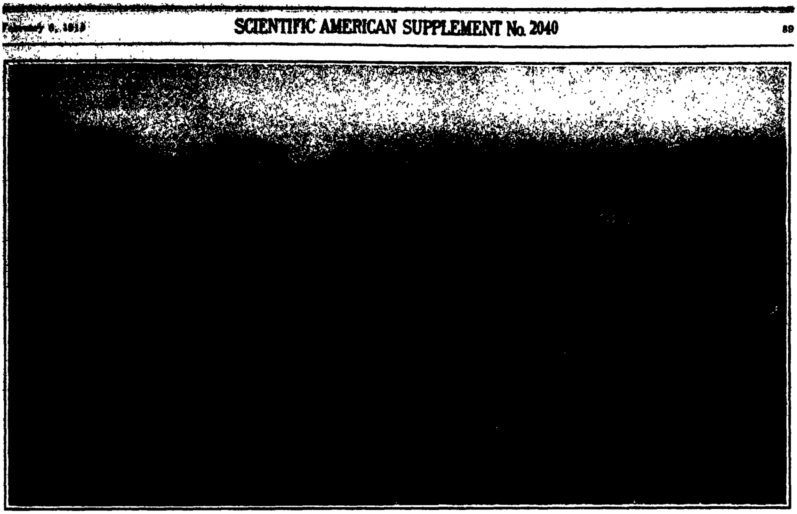
The Columbia Range consists in great part of ancient gneisses and schists the oldest rocks in the Cordillera These rocks formed at one time the old land mass which extended in a northwest southeast direction from Central America to the Arctic Ocean The greater part of this old land is buried under recent deposits or has been destroyed by the invasion of vast quantities of molten rock. The majority of these gneisses and schists are of sedimentary or waterlain origin and hence must have been derived from a still more ancient land now unknown and shrouded in mystery To the east and west of this old land lay basins in which sediments derived from it by agents of degradation accumulated in vast quantities, for the most part, on an ocean floor

The Eastern basin, or geosynclinal, which forms the subject of this article, includes the area now occupied by the Selkirk Purcell, and Rocky Mountain systems. The Selkirk and Purcell ranges, with a geological history similar to that of the Columbia Range consist in great part of bedded rocks of pre Cambrian age intruded by masses of igneous rocks of the granite family The Rocky Mountain system the youngest member of the Cordillera is composed almost entirely of bedded rocks ranging from early Palaeozoic to late Cretaceous while the Great Plains are underlain at the surface by deposits of Cretaceous and of Tertiary age

Deposits of the last geological epoch the Pleistocene or Glacial period are scattered sporadically over the entire Cordillera

BUILDING OF THE PURCELLS

If we could stand on the ancient land in the neighborhood of the Columbia range in pre Cambrian time to the west could be seen a rolling and monotonous landscape of moderate relief while to the east, as far as eye could see a shallow sea in which was being deposited sand and mud derived from the gradual wearing away of the old land by atmospheric agencies and by running water That this sea was shallow and remained shallow till Cambrian time is evidenced by the ripple marks, mud cracks rill marks, and the casts of salt crystals now preserved in these hardened muds At the dawn of the Cambrian period this ancient sea became greatly enlarged and mingled its waters with those of the ocean This mingling permitted the life which inhabited the ocean to invade the shallow continental sea, for it is in these deposits that we find for the first time definite fossil remains in the form of trilobites brachiopods and marine worms. After this period the waters in the sea gradually deepened and marine invertebrate life abounded This is shown by the presence of limestones containing abundant remains brachiopods corals, and lamellibranchs in the Devonian and Carboniferous formations of the Rocky Mountains. During Jurassic time represented by the deposition of marine, carbonaceous muds, the first forecasts of a great mountain building period were registered During the latter part of the Jurassic, or early Cretaceous the Purcell Mountains were built. They consist of immense folds of stratified rocks forming typically folded mountains strongly resembling the Juras of Europe and the Appalachians of the Eastern United States. The area affected by this folding is represented on our modern maps as constituting the land as far east as the Kootenay-Columbia valley or Rocky Mountain trench. It was in the neighborhood of this trench that the western [illegible]



Looking south along the range. Note the steep eastern and the gentle western slopes.

stood after the Jurassic Revolution. It had been shifted from the Columbia Range as far east as the western part of what is now represented by the Rocky Mountains.

THE ORIGIN OF THE ROCKY MOUNTAIN SYSTEM.

After the building of the Jurassic or early Cretaceous Mountains, they were at once subject to destruction by the agencies of erosion. The results of this erosion can be seen in the Cretaceous strata of the Rocky Mountain system. From a study of these strata, which for the most part are composed of conglomerates (water-worn pebbles) and carbonaceous shales (hardened muds) with which are associated many seams of coal and impressions of fossil plants, it may be concluded that at certain times the Cretaceous sea was shallow enough to have a dense jungle growth thrive upon its vast deltas formed from the material derived from the destruction of the Jurassic mountain ranges (Purcell and Selkirk) to the west. Sedimentation continued throughout the Cretaceous until sufficient stress had accumulated locally in this part of the earth's crust for the generation of another great mountain system, the Rocky Mountain system proper. For the formation of this great thickness of Cretaceous strata, the Purcell and Selkirk ranges were worn down to a low rolling landscape over which the meandering streams wandered sluggishly. This landscape, in technical language, is called a peneplain, and since it was formed during Cretaceous time, a Cretaceous peneplain.

At the close of the Cretaceous or in early Tertiary, the Rocky Mountains were formed. The earth's crust in this region was raised first in a series of gigantic folds with their longer axes trending northwest-southeast or parallel to the Pacific coast. In the eastern part of the range blocks of the crust were pushed up and carried bodily over the surface for a distance, in the case of the most eastern blocks seen east of Banff, of eight miles. Thus the Rocky Mountain system is a series of parallel ridges with steep faces to the east and gentle slopes to the west, and, in a view from one of the higher peaks, strongly resembles the parallel waves of the sea as they approach the shore. This simile is made more striking by the presence of the snow and ice on the northeastern slopes of the peaks in strong contrast to the deep green coloration of the forest covered valleys. In the picture the snow and ice sparkling in the sun represents the foam on the waves and the green forest, the cool depths of the ocean.

GNAWING OUT THE VALLEYS.

The initiation of a mountain chain by the folding of any portion of the earth's crust marks the beginning of its destruction. Rain descending on this elevated portion collects into streams which rapidly, in a young mountain range, gnaws for itself a valley in the folded strata. This first ridge probably will form the axis of the chain. The next ridge which rises will be the [illegible] tendency. The out-going stream endeavors to maintain its course to the sea across the rising ridge, which offers a barrier to its progress. From an examination of the transverse streams of the Rocky Mountains we see the victory invariably rested with the streams which now cut through the folds and fault blocks. These through-going valleys, making it possible for the trans-continental trains to reach the Pacific, have become the highways of commerce and travel. Such valleys are occupied by the Crowsnest Branch and the main lines of the Canadian Pacific and the Grand Trunk Pacific Railways.

These streams are termed antecedent streams since they kept their course in spite of the barriers raised (by the mountain uplift) against their progress. The longitudinal streams, on the other hand, occupy weak portions of the mountain area. In the Rocky Mountains they occur in areas of Cretaceous rocks which, being composed of soft shales, sandstones and conglomerates, are more easily eroded than the Devono-Carboniferous limestone on either side. These streams, called subsequent streams, since they are initiated subsequent to the mountain building, are tributary to the through-going or antecedent streams. The position of the valleys in the Rocky Mountains, in contrast to that of the Purcell Range to the west, depends entirely upon the structure of the mountains, that is, the drainage is impressed concordant with the folding and faulting of the underlying bedded rocks and hence the valleys belong to one cycle of erosion. In contrast to this, the drainage of Purcell Range is entirely independent of structure and its history can be referred to two cycles. In the first, during Cretaceous time, it was worn down to a peneplain, then uplifted concomitantly with the formation of the Rocky Mountain system. This uplift rejuvenated the streams, which again eroded out the present valleys which can be referred to the second or Tertiary cycle of erosion.

SCULPTURING OF THE MOUNTAINS BY GLACIERS.

The final molding of the Rocky Mountains into their present form is due to the erosive action of ice. An examination of any area within these mountains would show that the heads of nearly all the streams terminate in a beautiful lake or tarn nestling in a rock basin. The basins are called cirques and owe their origin to the work of snow and ice. The configuration of this mountain tract previous to the Glacial period was naturally marked by inequalities in the upland stretches and in these inequalities snow would collect which, on the arrival of the Glacial period, would not completely melt during the summer months and would continue to collect until, with the precipitation in the winter far exceeding evaporation in the summer, the collection of ice would slowly move down the slopes into the valleys. The inequalities which would be filled with snow would gradually enlarge by the movement of the water underneath the snow and even by the snow itself as it crept slowly down the slope. With increasing diameter these depressions would be occupied first by a permanent snowfield and finally by the névé of a glacier. Plucking action along the bergschrund would now rapidly push erosion headward. This action is well described by D. W. Johnson[1], who descended 150 feet into a bergschrund in a glacier in the Sierra Nevada. "It was in all stages of displacement and dislodgement, some blocks having fallen to the bottom, others bridging the narrow chasm and others frozen in the névé. Clear ice had formed in the fissures of the cliff, it hung down in great stalactites, had accumulated in stalagmitic masses on the floor." Here he states that for a considerable part of the year there would be "a daily alternation of freezing and thawing. Thus a cliff would be rapidly undermined and carried back into the mountain slope, so that before long the glacier would nestle in the shelter of its own making. The ice grips like forceps any loose or projecting fragment in its rocky bed, wrenches it from its place and carries it away. . . . as the cirques receded, only a narrow neck would be left between them, which would ultimately be cut down into a gap or col. Thus a region of deep valleys, with precipitous sides and heads, of sharp ridges and of more or less isolated peaks, is substituted for a rather monotonous, if lofty, highland."

From the above description it can be seen that the detailed beauty of the Rocky Mountain system with its castellated crags, horns, cols, aretes, and cirques, is not due to the forms originating with the building of the mountain ranges: this merely places the foundation for the subsequent superstructure which is created in its main outlines by the erosion of running water, while the final decorations are furnished by the artistic touch of snow and moving ice.

[1] D. W. Johnson; Science, new series, Vol. 9, 1899, p. 106.

Explosion of an Electric Transformer

The explosion of a large electric transformer in South Africa appears to have developed a new fact that was not before known. In taking down the transformer for repairs the workmen proceeded to drain the expansion tank located above the transformer of the oil it contained, and before doing so a workman held a lighted match over a sight hole in the tank, when a severe explosion occurred that either killed or severely burned every man present, besides setting fire to everything inflammable in the transformer chamber. As the oil in the tank was not above 34 deg. Cent., and its flash point was 140 degrees, the gas that caused the explosion could not have been oil vapor, and experiments were instituted using extra high tension discharges under transformer oil. Samples of the resulting gases were collected, which, on analysis, proved to contain at least 62 per cent hydrogen. It is evident from this experience that great care should be exercised not to allow a naked light near transformer oil tanks or oil switches until they have been thoroughly ventilated.

Protection from Earthquakes*

Principles of Location and Methods of Construction Found Desirable

By Th. Moreux

ALTHOUGH the definite prediction of earthquakes still presents serious difficulties, we have, at least, learned the location of the seismic regions of the globe, and, in general, the degree of instability of the soil therein. Hence arises the capital question: Must seismic regions be abandoned, or are there means of ensuring the safety of their inhabitants? The abandonment of such countries is, for material reasons, impracticable, but those who dwell in them should give heed to the facts stated below.

CHOICE OF A BUILDING SITE.

The location of a building in a region subject to earthquakes is by no means a matter of indifference, for within such regions some districts always suffer more severe effects from seismic shocks than others. Thus, during the great Lisbon earthquake of 1755 the lower portions of the town, built on alluvial or uncompacted tertiary soil, were devastated while the higher quarters, built on basalt, withstood the shocks quite well. At Aix-la-Chapelle, in 1877 and 1878, destructive effects were confined to the part of the town built on a loosely compacted chalk, while the quarter built on limestone did not suffer. At Tokio the higher part of the town, built on the rock, almost always suffers much less from earthquakes than the lower town, the soil of which is alluvial. Many other illustrations could be cited. Some exceptional cases admit of special explanations.

Soils consisting of alluvium or débris, *when they occur in a very thick layer*, offer an extremely favorable site for buildings. The reason is that they are very poor transmitters of seismic waves, which are propagated in them with as much difficulty as sound-waves in sawdust. This is true of alluvial strata whether lying underground or at the surface. Examples are found in the plains of northern Germany, the Russian steppes, the llanos and pampas of South America, and the prairies of Arkansas, where seismic shocks are almost unknown. These regions are, for the most part, characterized by the great thickness of their alluvial deposits.

On the other hand, if such strata are shallow, considerable movement will be felt. This apparent contradiction may be explained on the analogy of a mass of sand into which a cannon is fired, as in certain artillery tests; if the mass is thick it deadens the impact, while a small layer or pile of sand is scattered in all directions. Hence one should especially avoid placing a building on a thin layer of relatively loose soil overlaying a thick and solid stratum.

Generally speaking, anything which interrupts the homogeneity of the ground tends to increase the shocks transmitted. Location should, therefore, be avoided at the junction of two strata of very different material, as well as the vicinity of geological faults and the brows of cliffs and ridges. In such locations an earthquake produces a phenomenon analogous to that which is seen when a violent blow is given to the first of a series of billiard balls, lying in contact with one another; the shock is transmitted by the intermediate balls, but only the one at the other end of the row is set in motion. Villages and buildings perched on the side or crest of steep hills suffer severely in earthquakes; the superficial layers of the earth play the same rôle as the final billiard ball just mentioned; even solid rocks may be thus cracked or broken into fragments at the surface; long crevasses are formed parallel with the steep face of cliffs; and sooner or later landslips occur. In a similar manner, the banks of rivers may collapse, carrying down and destroying houses, roads, and cultivated fields. These facts illustrate the danger incurred in installing buildings, conduits, roads, or railways along steep escarpments in countries subject to earthquakes. The same considerations apply to railway embankments; they need to be flanked by very strong constructions.

To summarize—in "earthquake countries," or even regions of ordinary seismicity, it is advisable to avoid placing houses on lofty elevations, where the amplitude of seismic vibrations will reach a maximum, or on the slopes of hills and mountains. Plains and broad valleys offer a preferable location. Between two locations on loose soil, one should choose that in which the loose soil has the greater depth. In all cases one should take warning from the history of previous earthquakes; it should never be forgotten that it is dangerous to build on the spot where a well-constructed building has been destroyed by an earthquake, since like causes will again produce like effects.

FOUNDATIONS.

The question of foundations is very important. Shall we build on deep foundations, extending, if possible down to the subjacent rock? or shall we eliminate foundations altogether, and permit the building to rest directly on the ground? The experience of earthquake countries furnishes the answer.

It has long been known that seismic vibrations have a much greater amplitude—in fact, about twice as great—at the surface of the ground than at the bottom of an excavation some 10 feet in depth. It is therefore necessary to sink the foundations as deep as possible, and also to isolate them from the surrounding soil, in order to free them from the vibrations of largest amplitude. Thus at Tokyo several large buildings of the Imperial University resisted perfectly a number of violent earthquakes when neighboring buildings, constructed of equally solid masonry, were partly destroyed; investigation proved the different effects to be due to the fact that the buildings of the university had much deeper foundations than the others.

Whenever possible, the foundations should rest directly on the underlying rock. The regulations drawn up for the island of Ischia after the disaster of 1883 provided for cases in which the rock lay too far below the surface to be reached; under such circumstances the building was to be erected on a masonry or concrete platform two feet thick for a one-story building and 4 feet thick for a two-story building; and the platform was to extend from 3 to 5 feet beyond the base of the building. In Manila the regulations provide that the foundations shall be strong enough to support twice the weight actually placed upon them. Whenever the underlying ground is unfavorable, the foundation of a building should form a united whole, so that the different parts of the superstructure may be subjected to the same shocks. Cases are common in which disastrous effects have been due to the fact that various parts of a structure did not undergo simultaneous vibrations. Many remarkable examples are found in the history of railway bridges, as recorded in the reports of Omori and others.

Regulations in force in countries subject to earthquakes permit the construction of cellars, and even of vaulted ceilings therein; but these ceilings must be "full centered." Above the ground vaulting is always forbidden, as it tends to spread the walls.

Milne also mentions a method of making the building independent of the ground on which it rests, which consists of placing it either on cast iron balls or on two sets of iron rollers at right angles to each other, these resting on a floor of concrete. Such arrangements would, however, be suitable only for very small buildings and would provide no immunity from vertical displacements.

It has often been noticed that crevices and especially caverns in the ground oppose an obstacle to seismic movements. In Santo Domingo deep excavations are made in the ground near houses to insure the stability of the latter. Pliny believed that Rome was protected from earthquakes by the Catacombs. On the other hand, it should be remembered that subterranean galleries necessarily diminish the strength of the ground and introduce a new danger which is certainly not compensated by their diminished capacity for transmitting seismic waves.

Practically, in regions where earthquakes are not of extreme violence, it will suffice to build foundations very deep and at least twice as thick as they are ordinarily built elsewhere. If there is a vaulted cellar, its roof should be full-centered. Only the best and strongest materials should be used. Foundation walls increasing in thickness with depth are sometimes employed in Japan, and can be recommended.

WALLS AND CHIMNEYS.

In most cases it is the highest buildings which suffer most severely. The reason is obvious; if we shake a young tree by grasping its base, we shall see that the highest branches undergo the most violent movement.

Various regulations as to the height of buildings and the number of stories have been promulgated in earthquake countries. In Manila only the walls of the ground floor may be of masonry; the second story must be of wood. In order to diminish the weight of material the use of hollow bricks is to be recommended.

In an ordinary house consisting of four walls forming a rectangle, it is important to prevent the separation of the walls at their angles of junction, and various systems of iron frames and tie-beams built into the masonry have been proposed to prevent such separation. It is certain that a house forming an absolutely rigid and indeformable box would be the ideal plan, but it would be extremely difficult of realization, especially in the case of large buildings. Iron built into masonry does not form a homogeneous whole. Walls and floors bound together with metal tie-beams may not vibrate in unison, and this is one of the most serious causes of disaster.

In Japan the light houses of wood and paper suffer comparatively little injury, and the damage would be still less if the walls were fastened together at the bottom with wooden girders. In Santorin the people from time immemorial constructed their houses in the form of a monolithic box, without bottom, simply resting on top of the ground. They are built of a kind of cement consisting of lime and crushed lava. Openings are reduced to a minimum, and the vaulting is very thick. The roofs crack without falling.

In recent years the use of re-enforced concrete has been widely recommended, and it is certain that in this form of construction the problems seem to be solved, since all parts of the building—walls, ceilings and floors—are tied together. Re-enforced concrete has been much used in re-building San Francisco. This mode of construction is still so new that we cannot pronounce definitely in its favor, but it is highly probable that buildings thus constructed would merely fracture or crumble more or less without falling, and this would be a real advantage to their occupants.[1]

The openings in the walls are points of weakness and are often a cause of ruin. In Italy the regulations require that these shall be placed vertically one above the other. This is an unwise rule; a wall in which all the windows are in line vertically is virtually divided up into several parts and loses all power of resisting shocks. Milne, on the contrary, recommends that no two windows be in the same vertical line, regardless of the number of stories. The doors and windows should, moreover, be placed at some distance from the angles of buildings.

The shape of the openings is also of much importance. After the earthquake of 1885 in Tokyo, a careful examination was made of the European buildings in the Ginza quarter, and it was found that in all cases the windows in which the arches sprang sharply from their abutments had cracks running from the angles, while in those in which the arches curved out gently from the abutments there were no cracks, except in cases where the arches supported balconies. This example clearly indicates that only round-arched windows are admissible in a masonry wall. Stone balconies should be rigidly prohibited, as under shock they crack the walls or may fall upon the heads of people rushing from their houses. The same remarks apply to ornamental stone cornices and balustrades, and to heavy ornaments on ceilings.

Stairways should, as far as possible, be independent of the walls, as otherwise they play the same destructive rôle as balconies. Chimneys have been the cause of many accidents. At Charleston, in the earthquake of 1886, out of 14,000 chimneys, 13,200 fell. It is a good rule not to let them extend above the roof; they can be prolonged upward by means of a light sheet-iron pipe supported by somewhat slack guy-wires. The body of the chimney should not be built into the wall, which it would tend to crack in an earthquake, but may be placed in contact with it.

As to masonry materials, these should be of the very best quality; and in the superstructure preference should be given to materials combining a maximum of resistance with a minimum of weight. In very many cases where houses crumble at the first shock of an earthquake, the blame may be laid entirely on the inferior quality of the material, or a defective assemblage of stones and brick; in short, upon the neglect of the most elementary principles of construction.

ROOFS AND JOISTS.

However, in the course of my investigations in Provence after the earthquake of 1909 I observed many cases in which very solidly constructed buildings had collapsed like the rest. The reason was obvious. When the walls first oscillated under the action of the seismic wave, the joists were pulled out of their sockets and the ceilings descended en bloc; after the shock, the walls which, in virtue of their elasticity, tended to regain their equilibrium, were obliged to give way to the wedge-like pressure of these beams. This effect was due to the fact that, as a rule, joists are merely supported

* Condensed translation of a chapter in his "Les tremblements de terre," 2nd ed., Paris, 1909.

[1] There was only one large building of re-enforced concrete in San Francisco at the time of the earthquake of 1906, and this was unfinished. It resisted both the earthquake and the fire satisfactorily. During the recent great earthquake in Italy it is said that, in some places, the only buildings that remained standing were those of re-enforced concrete.—[illegible]

at the inner border of the walls, instead of passing entirely through the latter Hence, in an earthquake, the various stories fall on top of one another inside the walls. In order to prevent this, the beams should extend through the walls and project a foot or more on the outside, forming a sort of corbeling or balcony, such as we see in many mediaeval houses.

Analogous principles should guide us in the construction of the roof It is easy to see that if the latter is very heavy, when an earthquake occurs the whole roof, in virtue of its inertia, will behave like the steady mass of a seismograph, i e, it will not participate in the movement of the building beneath it The result is that either the walls, in their oscillation will slip away from the beams supporting the roof permitting the latter to fall and carry the edifice with it, or the walls will have a tendency to break halfway up, owing to the fact that their upper portions, which are fastened to the roof do not vibrate in unison with the lower portions Hence the roof should by all means, be made as light as possible, and it will be necessary to abandon conventional building methods in order to effect this

The necessity of doing so will appear from the following figures Roofing of flat Burgundy tile for a building 10 by 5 meters (33 by 16 feet) would weigh 9 900 pounds If we use the lighter mechanical tile the weight will still be between 3,500 and 5,000 pounds These figures do not include the weight of the woodwork of the roof A slate roof, though lighter than tile would weigh 2 200 pounds, not including the woodwork Evidently with any of these materials we place an enormous weight on top of our building, and it will not be surprising if seismic vibrations cause a rupture between walls and roof

The remedy has been sought in zinc or galvanized iron, either of which weighs about one-eight as much as flat tiles The weight of such a roof of the above dimensions, would not exceed 1 300 pounds but its use has serious structural disadvantages A metal roof is subject to deformations due to heat and cold and the greatest precautions must be taken to make it watertight Moreover these roofs are very hot in summer and cold in winter, so that one or two false ceilings must be used under them and this means added weight and expense

I sought for a long time a roofing material that was free from all these disadvantages In twice building my observatory I needed a covering for the dome and the roof that would combine lightness and solidity, and I found these conditions realized in a material which although not new is less well known than it deserves to be It is called 'ruberoid' and is a sort of woolen felt, impregnated with a simple waterproofing composition It comes in long rolls and is equally suitable for flat and sloping roofs Most of the new wooden buildings at Messina erected since the great earthquake are covered with this material which is not affected by variations of temperature

A covering of 'ruberoid' for a roof of the dimensions mentioned above weighs just 209 pounds i e, about 1/45 as much as one of ordinary tile and 1/20 as much as one of mechanical tile When I add that, by building the roof flat, we do away with the heavy timbering needed in a sloped roof, it will be seen that the use of this material is plainly indicated for earthquake countries

The use of a horizontal roof not only ensures lightness but also obviates one of the common dangers of earthquakes, when many persons are killed or injured by the fall of tiles and slates from sloping roofs Whatever covering material is adopted, the joists of the roof should extend from 1½ to 2 feet beyond the walls

CONCLUSIONS

The following is a summary of the essential facts deduced from the above discussion

Having chosen a suitable site, we may adopt one of two different plans, according to whether we propose to erect a large and costly building or a modest dwelling In the former case we must endeavor to secure great rigidity by the use of relatively heavy material The foundations will be thick and deep; the masonry very carefully laid, and the walls securely joined at the angles If the cellar is vaulted, the vaulting must be full-centered and very thick There should only be two stories, and the joists supporting the second must at least run through the whole thickness of the walls, to prevent them from being pulled loose The openings will be planned in accordance with what has been said above They should be rather narrow, and round-arched A light roof, with joists extending beyond the walls, is essential. In order to lighten the upper story the latter might be constructed of hollow bricks Stout inside walls will add much to the solidity and rigidity of the building.

In the case of the ordinary dwelling, flexibility should be preferred to rigidity, and we should seek to construct a house analogous to a wicker basket. A skeleton of wood or iron, very securely tied together, will always [illegible] especially if the building has but [illegible] walls presents serious [illegible] less protection from extremes of temperature a better plan would be to adopt the system of 'barrack' construction popular in Italy According to this plan a frame of wood or metal is filled up with as light walls as possible consisting of hollow bricks or other material of slight density

Two important principles should never be forgotten in any form of earthquake construction viz avoid weight of material unless accompanied by a corresponding degree of solidity and seek to unite to lightness and strength a certain amount of elasticity

The Causes of Solar Heat*

By A. Veronnet

THREE different hypotheses have been advanced to explain how the sun has for ages been emitting substantially the same quantity of heat viz by chemical reaction by intra atomic energy (such as is exhibited by radium) and by the attraction of gravitation Some precise calculations based upon recent data seem to indicate that the last theory advanced by Helmholtz is the one that is most tenable

The sun emits about $5 \cdot 10^{33}$ calories per annum and its mass is $2 \cdot 10^{33}$ grammes Even if the maximum calorific capacity be placed at 1 its temperature would fall by at least 2.5 deg Cent (4.5 deg Fahr) each year But the average temperature of the earth measured in degrees absolute is directly proportionate to the temperature of the sun Let us take 6 000 degrees and 293 degrees absolute (20 deg Cent) as the average temperatures for sun and earth It may be calculated that the earth's temperature on the surface would fall to 0 deg Cent (32 deg Fahr) after the short period of 165 years if this heat is not in some way replenished.

Chemical Reaction —The condensation of vapors and the formation of chemical compounds can occur below only the critical or dissociation temperature which latter is very near 5 000 degrees or 6 000 degrees for heavy metals and refractory oxides Now no known chemical reaction can develop 5 000 calories per gramme (the maximum of 4 700 degrees is obtained by the combustion of lithium) The entire mass of the sun would then be able to supply through condensation or combustion at the most $5\,000 \times 2 \cdot 10^{33}$ calories or sufficient heat for 2 000 years

Intra Atomic of Decomposition —This is much greater than the energy of combination but its effects are also much slower although it amounts to billions of calories per gramme It is admitted that all substances are subject to slow decomposition liberating this internal energy in the process but the phenomenon is perceptible only in the case of radio active substances and is most pronounced for radium It is known from the latest calculations (table issued in *Le Radium* January 1914) that 1 gramme of radium liberates 132 calories per hour let us say $1.2 \cdot 10^{6}$ calories per annum In order to account for the radiation of the sun it would be necessary to assume its radium content to be $4.2 \cdot 10^{27}$ grammes or 2 grammes per metric ton which is a higher percentage than that of the richest known minerals.

But the activity of radium decreases with time and would be reduced by half after some 1 700 years (S Meyer Sitzb Wiss in Wien March 1914) and this quantity of radium could not maintain heat and life in the sun and earth for over 2 000 years unless it could be renewed It is true that uranium is transformed into radium the constant ratio between the two substances being about three tons uranium for one gramme radium after the calculations of Strutt, Eve Cove and Boltwood (the constancy of this ratio is however called in question by some calculations of Miss Ellen Gleditsch, *Comptes Rendus* volume cxlviii 1909 page 1451) According to these figures the whole mass of the sun would have to be composed of uranium in order to keep the necessary quantity of radium constant during a sufficient length of time

Besides, the alpha rays of radium may be projected from helium, at all events radium is transformed partially into helium and 1 gramme of radium supplies yearly 158 cubic millimeters of helium or $2.8 \cdot 10^{-5}$ grammes, together with $1.2 \cdot 10^{6}$ calories The production of 1 gramme of helium corresponds with a release of $1.2 \cdot 10^{6} : 2.8 \cdot 10^{-5} = 4.3 \cdot 10^{10}$ calories. If we are able to estimate the quantity of radium in the solar atmosphere we can thus obtain the amount of heat which the radium contained in the sun has been supplying

It has been possible to determine the pressure on the surface of the sun or at least above the helium zone through the displacement of the lines of the reversing layer Buisson and Fabry (*Comptes Rendus* March 15th 1909) estimated this pressure at 4 to 6 atmospheres Jewell Humphreys and Mohler (*Astronomical Journal* volume iii page 139) place it at 2 to 7 at mospheres Evershed (Kodaikanal Observatory No 18 1910) calculate it to be as low as 0.13 atmosphere on an average Let us concede a maximum pressure of 10 atmospheres gravity on the sun being twenty-eight times as great as it is on the earth the whole atmosphere of the sun must have a mass of about $10 : 28 = 0.35$ kilogramme per square centimeter (almost 5 pounds per square inch) that is to say $340 \cdot 6 \cdot 10^{20} = 2 \cdot 10^{23}$ grammes Supposing it to consist entirely of helium it would correspond to the liberation of

$$2 \cdot 10^{23} \cdot 4.3 \cdot 10^{10} = 8.6 \cdot 10^{33} \text{ calories}$$

which represents heat enough for only 170 years. This is the maximum supply of radium.

Besides, the percentage of helium in the solar atmosphere is rather low as it does not give any black line in the spectrum and its absorption is not marked It is probable the above figure ought to be divided by 100 or 200 It must be concluded therefore that intra atomic energy cannot have noticeably intervened in the maintenance of solar heat

Gravitation —It has been suggested that meteorites dropping into the sun or the fragments of a comet may be responsible for solar heat But while the mass of sun would increase the time of revolution would decrease Taking into account Kepler's third law and the decrease in the amount of motion we easily obtain the formula M^3T = constant The oldest observations show that the year is decreasing by 0.53 second each century Attributing this variation solely to the increase of the mass of the sun and differentiating the foregoing formula we find $1.67 \cdot 10^{20}$ grammes as the maximum annual increase The energy produced by a mass of 1 gramme falling on the surface of the sun may be calculated as equal to $2 \cdot 10^{15}$ ergs and this increase in mass produces at the most $8 \cdot 10^{27}$ calories per annum or four hundred times less than necessary for the maintenance of solar heat

Hence there is but one hypothesis left—that of the generation of heat by the contraction of the sun itself, and this alone can and must account for all the heat the sun is radiating This contraction could account for an amount of energy or work equal to twenty million times the amount of energy the sun is radiating every year at present This moreover is a maximum and it has been shown (*Comptes Rendus* February 9th and 23rd 1914) that, considering the fact that the radius and temperature of the sun were both greater in the past it must be admitted that radiation and loss of such heat required a little less than two million years. The sun in its present condition and life upon the earth can be traced back about two million years. The conclusion may therefore be drawn that the temperature upon the earth will not fall below 32 deg Fahr in less than two million years to come a period which will undoubtedly be prolonged by the fact that the earth is drawing nearer the sun

It is true that geologists claim one hundred million years and more to have been necessary for the formation of the geological strata But they are measuring erosion on the basis of the present causes acting with present intensity Erosion is caused by the heat of the sun which produces clouds and rain We have here a sort of heat engine and we know in such a case that the more powerful this engine is the greater the results The contraction of the sun allows us to dispose of an amount of heat equal at the maximum to twenty million times that which it is radiating at present per year and admitting that this heat is spent over two million years instead of twenty million we must multiply the power of erosion by 10 (see Hermann Hypotheses cosmogoniques modernes 1914 page 139) It can also be admitted that the product was multiplied by 10 making thus erosion work equal to that which would require two hundred million years the present rate and calculations of both geology and celestial mechanics will thus be made to agree.

*Translated for SCIENTIFIC AMERICAN SUPPLEMENT from Cosmos.

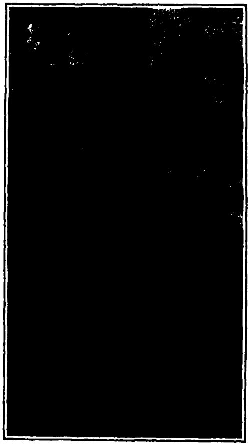
Electric Lighting on American Railways

THE statement was recently made that the number of cars on American railways lighted by electricity had increased from about 11 000 in 1911 to nearly 19 000 in 1914 a growth of 72 per cent The greatest part of this increase uses the storage battery and axle generator system while the head-end installations have increased but one third this amount Of the storage batteries there are in use about 260 000 lead battery cells and 32 000 of the nickel iron cells but this latter figure represents an increase of six times in the last two years

The Canon Ball Tree of Tropical America

THE cannon ball tree (*Couroupita guianensis*) is one of the most curious trees in tropical America. It is so called because the fruit resembles a cannon ball. Although the tree is sometimes referred to in botanical literature as the bullet wood or nutmeg these names are almost never applied to it in the region where the tree grows. The French have named it *arbre à bombes*, *boulet de canon* and the popular German names are *kanonenball baum* and *kanonenkubelbaum*.

The cannon ball tree may be said to be large but it does not vie in height and diameter with the majority



The cannon ball tree in flower

of other trees in the tropical forests. It seldom develops a long trunk which is rarely three feet in diameter four feet above the ground and only from ten to twenty feet to the first branches which are usually spreading or partly ascending forming a broad irregular or round depressed crown. While the tree often attains a total height of sixty to ninety feet in the forest, in the open it seldom grows so tall but its crown is more spreading.

The tree is confined largely to the low moist land skirting the rivers but it never occurs in great numbers even where the conditions are most favorable for its best development. One may travel for miles in the dense tropical jungle without seeing a single tree of this species. It is believed that the northern limit of its distribution is in the Republic of Panama where it has been reported by only a few botanists. During the recent biological survey of the Canal Zone a specimen of this species was discovered growing just south of the city of Panama and it appeared from the available data that its range of growth extends from this point in Panama southward and eastward to the mouth of the Amazon River. It is found on the island of Trinidad but it is more common to the low moist soil of the mainland especially in the Guianas.

Several beautiful trees are growing in the public parks in Port of Spain, Trinidad, and also in the botanical garden in Georgetown, British Guiana, and very few visitors to these cities who are interested in nature fail to see these curious trees. It is a rapid grower and quickly forms fine features as a specimen plant in a tropical garden. It suddenly drops its leaves in March and in a few days is again clothed in fully developed foliage of the richest green. The flowers are large, abundant, very curious in form, pink in color and highly scented.

There is hardly another forest tree in the world that bears its fruit similar to that of the cannon ball tree. The fruit is a large woody globular pod about six or eight inches in diameter resembling a cannon ball. The shell or pericarp is thin, smooth, grayish brown or rusty colored, and has a circular scar near the center which marks the point where the calyx or outer floral envelope became detached from the young unripe fruit. The shell when opened at this scar and the pulp and seeds removed is often used in tropical America for domestic purposes as a calabash. The pulp which surrounds the seeds possesses an agreeable flavor, and when nearly ripe is often employed for making a refreshing drink in case of fever. This pulp contains sugar, gum and malic, citric and tartaric acids. The over matured fruit possesses a very disagreeable odor which is remarkable for its penetrating and lasting properties. The seeds of which there are a great many in each fruit, are flat, circular and rather larger than a dime. They are imbedded in the pulp from which they are easily separated upon maturity. As will be seen in the accompanying illustrations the fruit is borne in clusters on the trunks and large lower branches, and not near the ends of the small branches or ultimate twigs as in other trees.

The Explosion of Kerosene Lamps*

EVERY little while we hear of the explosion of a kerosene lamp attended by serious injuries to persons who happen to be near. In the public mind there is something mysterious about these lamp explosions—something that calls for explanation. They are usually attributed to the poor grade of the oil or to some other cause unknown to the owner or user of the lamp or beyond his or her control. Various persons either in good faith or otherwise have tried to make capital out of the widespread feeling of distrust that the public has toward kerosene lamps. Some years ago for example there was a heavy demand for a certain bluish powder that was to be placed in the reservoir of the lamp and which was guaranteed to protect it against explosion. Of course most of the lamps that were protected by this powder did not explode but that was only because few lamps explode anyway. There is no reason whatever to suppose that the *proportion* of explosions was any less among the lamps "protected" in this way than among those that were not "protected."

There is nothing actually explosive about *the oil itself* whatever its grade may be. Explosions are due to the ignition of mixtures of *oil vapor* and air and they are more likely to occur when using a low grade oil than when using one of a higher grade because the low grade oil contains a larger proportion of light volatile hydrocarbons and it therefore gives off vapor more freely. But whether the oil be high grade or low grade its vapor will not explode unless it is mixed with air in a suitable proportion and fired by direct contact with a spark or a flame.

The quantity of oil vapor generated in the reservoir of the lamp depends upon the temperature of the reservoir as well as upon the nature of the oil—a high temperature causing a marked increase in the vaporization. It is therefore advisable to keep the temperature of the oil reservoir as low as practicable. To some extent this is a matter of design and it is almost impossible to prevent the reservoirs of metal lamps burning large quantities of oil from becoming heated to a temperature high enough to produce marked vaporization. All lamps should be kept as cool as their construction will permit however. For example they should not be allowed to stand on over or near hot stoves, registers or radiators. They should also be kept as nearly full as practicable so that the space occupied by the oil vapor may be small.

If the upper part of the reservoir of a lamp is occupied by an inflammable mixture of oil vapor and air it is still not dangerous unless flame gets access to it. In fact, when a lamp explodes the trouble is far more likely to be with the lamp itself or with the way it is used than with the oil, although prudence always indicates that the oil should be of the best quality obtainable, with a high flash point, so that any chance communication of flame will be unlikely to lead to serious results.

For flame to gain access to the interior of the reservoir there must be an opening of some kind through which it can pass. The opening may be due to the omission of the plug or cap from the filling aperture or it may be due to a break in the reservoir or to other causes. More often however the explosion takes place because the wick does not fit the lamp properly. If the wick is too small so that a considerable space is left on one side of it gas may escape in this way taking fire and carrying the flame down into the reservoir if the opening is big enough. This action may be assisted or precipitated by blowing down into the top of the lamp to put it out, or by the chilling action of a draft of cold air striking against the outer surface of the reservoir. If there is a considerable volume of mixed air and vapor in the reservoir in a highly heated condition, a sudden cold draft may cause it to contract quickly enough to draw the flame down into the reservoir, with an explosion as a result. Lest timid householders who may read this warning should be unnecessarily alarmed about the condition of their lamps, we desire to assure them that there is no danger of the kind described unless there is a plainly visible opening of considerable size down along one edge of the wick. The wick should be loose enough to work freely, for if it fits too tightly it will not turn up and down readily, and if it jams in its tube the oil will not draw up well, and the lamp will not burn properly.

By examining any properly-constructed kerosene lamp it will be seen that there is a small vent pipe, usually very much flattened extending upward through the burner in such a way as to put the interior of the reservoir in free communication with the space immediately adjacent to the flame. This tube is provided in order to equalize the pressure inside the lamp with that of the surrounding air of the room. This little tube should be kept free but care should be taken not to increase the size of it in any way. It is a well known fact that flame will not pass through very small openings, and the maker of the lamp knows just how large this vent pipe can be made and what shape to give it, so that it will fulfill its purpose without permitting the gas-mixture in the reservoir to take fire from the flame of the lamp. As the lamp leaves his factory the vent pipe is of a safe size but if it is enlarged to any considerable extent by thrusting things into it when cleaning the lamp it may become a source of danger.

Finally the operation of filling should never be carried out while the lamp is burning nor while it is standing near any lighted lamp or gas jet or near a stove with a fire in it.

If the various points that we have mentioned receive careful attention there need be no fear of a lamp explosion except as the result of dropping the lamp or subjecting it to other rough and unreasonable usage for which it was never designed.

* The Travelers Standard.

New Three-phase Motors

ONE of the recent ironclad three-phase motors of Swiss make embodies some original features, and is the result of careful study in order to produce a substantial motor for certain classes of work. What is desired here is a nearly or all inclosed motor of moderate size with forced draught so as to allow of its use in damp places. For very wet localities or those containing acid fumes, the motor is entirely inclosed. An air fan at one end of the armature creates a suction through one leg from the flow beneath and the air traverses the motor and descends through the other leg of the motor. An original idea lies in the working of the starting resistance. This consists of a disk resistance coil on the motor shaft next the air fan and from here run six copper rods clear through the armature to the other side. A large copper ring slides on all six rods, which have an equal length, so that sliding the ring along the rods by a hand wheel mechanism short-circuits the rods successively. In this way no slip rings or brushes are needed. An outside hand wheel operates the sliding of the ring which of course rotates with the armature, and the same mechanism serves to throw the main switch of the motor.

The Gas from Blast Furnaces—I*

Its Cleaning and Utilization

By J. E. Johnson, Jr.

The realization of the great heating value of the top gases of the blast furnace was very slow in taking useful shape. For centuries, furnaces ran with their tops wide open, discharging the gas into the air, with which it united in a great column of flame, visible for miles by night, even in the smaller furnaces of that early day.

Even after the invention of the steam engine, the possibilities of blowing furnaces by steam power were not practically realized for several decades and furnaces continued to be located primarily with reference to a suitable water power for blowing. In the same way after the invention of the hot-blast in the third decade of the nineteenth century the stoves were not at first heated by gas from the furnace, but were independently fired with coal.

Later a small chamber filled with iron pipes was built over the top of the furnace and the flame from the open top passed up through this, heating the blast which passed through the pipes. Still later flues were built into the brick work near the top, but just below the stock line and connected with a powerful chimney whose base was approximately level with the top of the furnace; this chimney drew some of the gas from the furnace, naturally much mixed with air drawn in from above, and the mixture burnt on its passage from the furnace top through the boilers and stoves to the chimney.

The final step was taken by closing the top of the furnace with a huge conical valve called the "bell" and forcing the gas by the pressure from below out through the flues into a pipe leading down to the ground level, where the stoves, boilers and stacks were located. This pipe early received and still retains the name of the "down-comer."

These top gases in Lake ore practice contain about 50 per cent of the total thermal value of the fuel charged. In districts where leaner ores are used and more fuel is consequently required per ton of iron the gas is correspondingly richer and contains a proportionately larger percentage of the thermal value of the fuel. In Lake ore practice an average analysis is about as follows: carbon monoxide 25½ per cent, hydrogen 3 per cent, carbon dioxide 12½ per cent, nitrogen 59 per cent. The thermal value comes entirely from the two former components.

The hydrogen comes partly from the moisture in the blast which is dissociated in the hearth, and partly from the moisture of the charge which is decomposed in the upper levels of the furnace. This gas under standard conditions of 32 deg. Fahr. and 30 inches of mercury contains from 94 to 102 British thermal units per cubic foot and has a specific heat of about 0.02 per cubic foot so that it contains about 2 British thermal units of sensible heat for each 100 deg. Fahr. above that temperature.

This gas is then somewhat more than half as high in heating value per cubic foot as ordinary producer gas. This, with the enormous volume produced (some 140,000 cubic feet per ton of iron in good practice and more where the practice is poorer), gives it enormous commercial value, so great in fact as to equal a considerable percentage of that of the pig-iron itself.

This gas having been in intimate contact with the charge in its course up through the furnace, and having carried off all the moisture of the charge not dissociated necessarily contains much moisture and picks up much fine dust from all the different components of the charge. It also carries a fume consisting of solids volatilized in the hearth of the furnace which sublime into the solid state, but in the form of an impalpable powder, as the gas cools in its progress toward the furnace top.

It is this fume that gives the gas its characteristic appearance, so that an experienced furnaceman can tell more quickly by looking at the gas discharging from the boiler and stove stacks than by any other way if his furnace is working "hot" or "cold," since a relatively few degrees drop in hearth temperature make a great difference in the amount and appearance of the fume thrown off.

The composition of this fume will be treated more at length in a subsequent article; for the present it is only necessary to say that it consists mainly of silica, alumina, lime, potash from the ash of the coke, and iron, and in case the charge contains much manganese, this element is present in the fume to a great extent, changing the white color of the fume of a good working furnace [illegible] to a light yellow when running [illegible] and to a dark yellow or brown when running [illegible].

In the early days of slow driving the velocity of the gas current through the furnace was small and the quantity of fine ore in the charge was almost negligible in comparison with the quantity of fine ore used to-day, which runs from 50 to 100 per cent Mesabi in the majority of American practice.

Under those conditions a single, comparatively small outlet at one side of the furnace top was sufficient and the quantity of dust carried by the gas was extremely small, therefore a single pipe of moderate size running straight or almost straight down and branching directly off to the stoves and boilers was all that was necessary to handle the gas. This constituted but a small, almost an insignificant fraction of the plant as a whole. Conditions at the present are vastly different from this in three respects:

First, the velocity of the gas through the furnace is several times greater than it was in those early days and the carrying power of the fluid current increases at an enormously rapid rate with an increase in velocity. I have seen the statement that this increase was as the seventh power, which would mean that doubling the velocity would increase the quantity of material carried 128 times. Whether this be true or not it is certain that the rate of increase in carrying power is extremely high.

Second, the ore used instead of being practically all hand-prepared lump consists very largely of fines, much of which is capable of passing through a 100-mesh sieve

Third, we have come to realize the enormous cost of attempting to utilize gas in its dirty condition for stoves and boilers, even leaving out of consideration gas engines, which require gas cleaner than the air we breathe for their successful operation.

These three causes have had an enormous effect on the gas-handling system of the furnace which has in recent years become one of the largest and most conspicuous features of the whole blast furnace plant.

THE OUTLETS FROM THE FURNACE TOP.

From the time of the closed top or soon thereafter, some furnacemen claimed that the gas should be taken off either from the center of the furnace or at several points symmetrically arranged around the furnace top. Others claimed that the gas, having gone through the stock column, had done its work and that the location of the outlet was a matter of no importance, and that one large outlet located on one side was cheaper and simpler than any other arrangement and just as good.

In connection with furnace tops, I shall show a design of top arranged to take the gas out at the center, which worked successfully for many years and gave but little trouble. It was, however, impossible to make the top quite so simple in this way as with the outlet on one side, and so the great majority of furnaces built in the United States up to 20 years ago were constructed on the latter plan, although in discussing operation I shall show what is to my mind an indisputable proof that a single side outlet produces an unsymmetrical passage of the gas through the furnace and cannot lead to the best work.

As furnaces and their outputs grew they produced a vastly larger quantity of gas, so their designers provided more gas outlets, two and even up to five or six Good practice now very generally uses four, though in my judgment three properly located are sufficient.

DOWN-COMERS.

This introduction of multiple outlets introduced other difficulties into the design of the plant.

With a simple outlet the down-comer could drop almost vertically to the ground close to the base of the furnace, but with this growth of output, necessitating multiple outlets, came the vast increase of dust which I have mentioned and the necessity for providing some means for its removal. As long as the gas traveled on a steep downward slope, the dust would accompany it, but when the dust reached the horizontal passages leading to the stoves and boilers and from these to the stack, it settled in them and obstructed them so rapidly as to constitute a serious obstacle to continuous and satisfactory operation.

Means therefore had to be provided for the removal of the dust at the foot of the down-comer and for this purpose chambers, at first only a little larger than the gas mains were introduced, but as conditions grew worse and worse these were increased in size and required, therefore, to be placed further from the furnace in order to give the necessary room for operation.

This threw the foot of the down-comer away from the furnace at its base, while the necessity of reaching more than one outlet threw its top back, from the closest point on the top of the furnace shell, to the center line of the shell when the two outlets were used, and finally to the back or opposite side when four or more were used. These two factors flattened the slope of the down-comer from almost vertical to a slope well below 45 degrees.

In some of the earlier installations these conditions were made still worse because it was considered necessary to have the down-comer enter the top of the dust-catcher in the center of the latter and this reduced the vertical height, at the same time all the other factors above mentioned increased its horizontal reach. I think that the slope of the dust-catcher on some of the plants built about the time of the Duquesne revolution was not more than 30 degrees. These were extremely unsatisfactory in operation because not only would dust lodge in them but also coke and other materials from the charge; they did not free themselves under any circumstances and no matter how large they might be built, they filled up until the velocity of the gas through them was great enough to scour a passage-way through the accumulation on the bottom slope, this, of course, involving high top pressure and consequent leakage on every joint not tightly sealed.

EXPLOSION DOORS.

Down-comers are generally provided with explosion doors for two purposes. First, when furnaces are stopped it is almost impossible to prevent air being drawn into the gas main at some point or other. This air mixes with the gas and produces an explosive mixture. When operation is resumed this mixture is ignited at the boiler or stove burners and an explosion follows which in some cases is violent enough to burst the main, dust-catcher and down-comer unless it is relieved by suitable safety-valves or explosion doors.

Second, the furnace itself is liable to slips or explosions in which a pressure of several pounds to the square inch, ordinarily only occurring at the lower levels of the furnace, reaches the top and would do it great damage unless properly relieved.

This latter theory has been combatted by Mr. Julian Kennedy, who has claimed that explosions were more violent in proportion as they received freer vent; comparing the conditions which arise at such times to those occurring when the cork is removed from a bottle of charged water, if this be done suddenly a great proportion of the contents of the bottle is violently ejected, but if the cork is held back and the gas pressure allowed to pass off slowly, none of the contents of the bottle are thrown out. In accordance with this theory the tendency in recent years has been to provide many less explosion-doors than were formerly thought to be necessary, and the results have very largely confirmed the theory, though many furnacemen are not willing to go as far as advocated by Mr. Kennedy and do away with explosion doors entirely

One design, made about the time of the Duquesne revolution, was intended to be the best possible regardless of expense. Some five or six outlets were provided around the top of the furnace, and these were all connected with an annular main, from one or two points on which the branches of the down-comer led off. Explosion doors were arranged on the outside of this annular main, which, of course, was a few feet below the operating platform of the furnace top and in order to provide access to it a supplementary platform was built a few feet below.

This system has almost all of the disadvantages which could be worked into one design. On the side opposite to the down-comer there was so little current of gas that the annular main became sufficiently choked up to make it virtually useless and one or two outlets on the side next to the down-comer carried off all the gas, practically as though the annular main did not exist. On account of the large size and distant location of the dust-catcher and the wide stretch of its branches to reach the opposite sides of the annular gas main the slope of the down-comer was exceedingly flat, and it is probable that after it was in operation a short time more than half its area was choked up and not in active use. One of the worst features of the design was the location of the explosion doors which, it will be seen, came just under the main operating platform. Owing to the choked condition of the down-comer, the top pressure was high and the explosion doors were generally leaking more or less; if the gas caught fire it burnt underneath the top platform so as to damage the steel work, and if it escaped unburnt the gas came up onto the top platform in sufficient quantity to make

* [illegible] Metallurgical and Chemical Engineering.

it dangerous to stay there any considerable length of time.

It may not be amiss to say a word here as to the general design of explosion doors. These are always made hinged, but are located in two different ways; first, so that the plane of the door is horizontal when closed; second, so that it is steeply inclined or vertical when closed. The latter design is radically wrong and should never be used because the moment of the door due to its weight, is little or nothing when it hangs vertical, consequently a slight pressure is sufficient to force it from its seat, but as its moment rapidly increases a much greater pressure is required to force it to open wide as it should when it is needed at all.

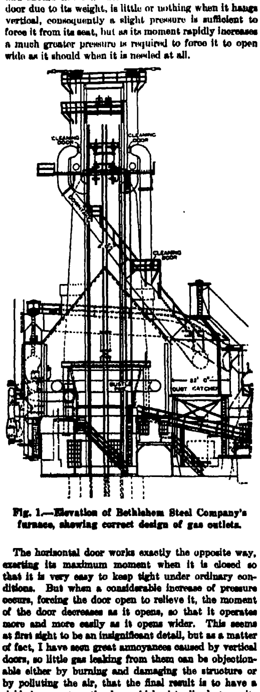

Fig. 1.—Elevation of Bethlehem Steel Company's furnace, showing correct design of gas outlets.

The horizontal door works exactly the opposite way, exerting its maximum moment when it is closed so that it is very easy to keep tight under ordinary conditions. But when a considerable increase of pressure occurs, forcing the door open to relieve it, the moment of the door decreases as it opens, so that it operates more and more easily as it opens wider. This seems at first sight to be an insignificant detail, but as a matter of fact, I have seen great annoyances caused by vertical doors, so little gas leaking from them can be objectionable either by burning and damaging the structure or by polluting the air, that the final result is to have a rigid clamp put on the door which virtually destroys its usefulness for its primary purpose even though it may not completely eliminate the leakage.

Fig. 1 shows a design of gas outlets and down-comer which secures practically all the important advantages. The drawing shows the "E" furnace of the Bethlehem Steel Company. The outlets are four in number rising from the conical top of the furnace shell. The down-comer instead of connecting directly with the outlet openings on the furnace shell on the back or high side, connects with the outlet pipes at a point several feet above the operating platform and thereby secures sufficient height to give it a slope steep enough to free itself. The explosion doors are placed on the top of these high outlet pipes many feet above the operating platform and if they leak no harm is done. If the gas burns it cannot strike anything to destroy, and if it remains unburnt it pollutes the air far above the heads of those who may have occasion to be upon the operating platform.

In the early days the down-comers were made of quite thin pipe entirely unlined, and these gave remarkably good service considering the relatively high temperature of the gas they sometimes had to handle, temperatures of 800 or even 1,000 deg. Fahr., in regular operation, being not uncommon, while, of course, very much higher ones occurred during slips.

In modern practice, however, the down-comer is always built of very substantial steel plate and lined with circle bricks from 3 to 4½ inches thick. This makes an almost indestructible construction but a very heavy one, so that due care must be taken to support the weight of the down-comer at both ends.

DUST-CATCHERS.

Dust-catchers were not considered a necessary part of a plant until within the last 20 or 25 years. The first ones were crudely designed, simply with the idea of providing an enlargement in the gas main in which the velocity of the gas would be reduced and its dust contents dropped to the bottom by this reduction in velocity. Ordinarily very inadequate means were provided to prevent the gas current from picking up again the dust it had once deposited, and the efficiency of the apparatus was in some cases so low that the quantity of dust recovered was inappreciable, and after several years trial the dust-catcher was thrown out and replaced by a plain section of pipe. Eventually the idea took shape of combining centrifugal force with the reduction in velocity to throw out the dust.

The sketch, Fig. 2, illustrates diagrammatically the construction which came to be standard for the first type. Fig. 3 shows an early type sometimes used to secure the centrifugal effect. The tangential inlet into the dust-catcher body constitutes the principal difference in the two types.

The difficulty of preventing the dust from being picked up by the gas current after being deposited, was a serious one, and its solution was sought by several furnacemen and several designs were brought out to overcome it by having the dust impinge upon the surface of water to which it would adhere and from which the gas could not pick it up again.

One of the earliest designs to embody this principle was that of Mr. F. E. Bachman, then manager of the Northern Iron Company, at Port Henry, N. Y. Mr. Bachman built a dust-catcher in general appearance not differing greatly from the ordinary type provided with a tangential inlet as shown in Fig. 3. The shell of this instead of being lined with firebrick, as in ordinary constructions, was sprayed inside with a great number of small jets of water which produced a water film running down over this whole interior surface. Centrifugal force threw the gas against this surface to which the dust adhered, and was carried to the bottom by the flow of the water film. The gas only being exposed to the surface of the water for a short time did not absorb enough water vapor to affect its thermal value materially. This dust-catcher was in operation for a number of years (as far as known to me it still is) and gave excellent results. The stoves remained clean and serviceable, although the furnace was charged exclusively with magnetic concentrates, which were quite fine.

Another design to secure this result was that of Mr. R. C. Steese, whose dust-catcher is shown by Fig. 4. The body of the dust-catcher is horizontal and filled with water to about one-third of its height. The gas enters at one end so as to impinge on the surface of the water and is reflected therefrom into a semi-circular passage which brings it back to impinge upon the water a second time. A second semi-circular passage repeats the operation once more and the gas is finally discharged at the far end of the dust-catcher.

This design avoids the maintenance of the sprays required by the Bachman apparatus, but, on the other hand, the surface of the water is not constantly and rapidly renewed as it is in the Bachman design, and this is a point of much importance because when the surface of the water becomes fouled by a heavy layer of dust, other dust impinging upon this is not held but liable to be picked up again and carried on by the gas.

Another dust-catcher which uses the principle of having the gas impinge upon the surface of water is the invention of Mr. B. F. Mullen, of Leetonia, Ohio. This dust-catcher has had the widest appliance of any apparatus of its type. The design is shown in Fig. 4a. The external shape of the apparatus is not unlike that of the standard dust-catcher. The gas enters at the top and passes into the central chamber shown. This chamber is suspended from the dome of the dust-catcher, its shell is lined with firebrick and its bottom constitutes a tube plate supported by the suspension rods *L*. Through the tube plate project a great number of short tubes through which the gas is forced to pass at a considerable velocity. The bottom cone of the apparatus is filled with water to a level from 4 inches to 6 inches below the bottom of the tubes. This level is maintained by overflow through the ports *H* around the circumference of the dust-catcher body.

Fresh water is introduced into the center through the pipe shown, and flows regularly outward to the outlet ports *H* through which it discharges. This keeps the surface of the water constantly in motion and prevents its becoming too foul to hold the dirt thrown upon it.

After the gas leaves the tubes and impinges upon the water surface it passes into the annular space around the central chamber and so to the outlet at the side. The top of the outlet trough just beneath the ports *H* is sealed by a conical plate, the bottom of which is riveted to the bottom of the trough, while its top is riveted to the shell of the dust-catcher proper.

The light dust which lodges on the surface of the water is carried away by the flow of the water, while the heavy dust which penetrates the surface is flushed off from time to time through the bell valve at the bottom of the cone. A later design is modified so that the outlet trough for the waste water is inside the main dust-catcher structure instead of outside of it, but the principle remains the same.

This dust-catcher has given very good satisfaction in use. The principal point to be guarded against is any fluctuation of the water level which will permit the end of the discharge nozzle to become wet, because, if they do so the dust will rapidly build upon them and in time

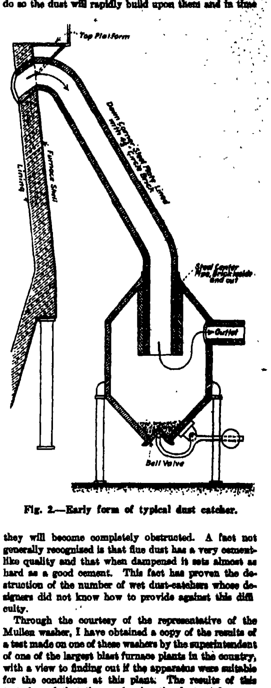

Fig. 2.—Early form of typical dust catcher.

they will become completely obstructed. A fact not generally recognized is that flue dust has a very cement-like quality and that when dampened it sets almost as hard as a good cement. This fact has proven the destruction of the number of wet dust-catchers whose designers did not know how to provide against this difficulty.

Through the courtesy of the representative of the Mullen washer, I have obtained a copy of the results of a test made on one of these washers by the superintendent of one of the largest blast furnace plants in the country, with a view to finding out if the apparatus were suitable for the conditions at this plant. The results of this test showed that the gas leaving the dust-catcher contained 2.28 grains per cubic foot of dust and after leaving the gas washer it contained 0.75. The representative of the gas washer claims that it is capable of doing considerably better work than this, but even this reduces to a third the total amount of dust carried into the stoves and boilers, as there is a very considerable proportion of the total dust carried through by the stack gases without being deposited; this reduces the proportion which lodges in the stoves and boilers, to their detriment, by a considerably greater percentage, and at the original plant where this washer was installed at Leetonia, Ohio, experience proved that they could run the stoves for the whole blast without taking them off the furnace for cleaning, which would be quite impossible without some means for reducing the dust in the gas far below the percentage which it contains on leaving the dust-catcher.

Many other types of dust-catchers have been built and tried out, but those described give the broad outlines of the art as it existed before the introduction of the gas engine. This forced a further step and a very long one in the direction of cleaning the gas, and as has so often happened, knowledge of the subject gained in learning to clean gas for gas engines has proven of great advantage in directions not contemplated when the work was undertaken. There seems to be definite limits to the degree to which the gas could be cleaned by any type of [illegible] centrifugal force, or [illegible] combination of any of [illegible]

as obtainable is barely sufficient for moderately good practice with the stoves, and as I have previously explained, great economies were effected by cleaning the gas a step beyond this point for use with stoves.

Most of the processes used for the next step in cleaning have involved scrubbing the gas with water and this introduced another element in the situation. The gas as scrubbed picks up water vapor enough to saturate itself at the temperature at which it leaves the scrubber and this has a somewhat complicated effect. The gas as it comes from the furnace at a temperature of 300 degrees to 500 degrees, carries a very considerable quantity

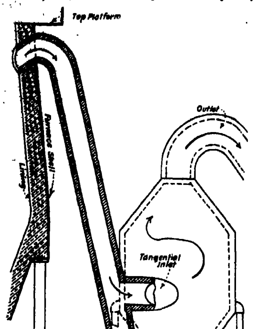

Fig. 3.—Typical form of centrifugal dust catcher.

of water vapor picked up from the stock, which, in a large proportion of modern practice, is heavily sprayed with water just before being charged into the furnace. This water vapor is somewhat of a detriment to the gas since it acts as ballast during combustion and prevents attainment of as high a temperature as would be reached with the same gas at the same temperature, dry. By scrubbing the gas with water this temperature is reduced and its saturation point is so much lowered that water may actually be removed from it instead of being imparted by the scrubbing operation.

It is obvious that we have here two conflicting effects. The reduction of the temperature of the gas itself is bad because the sensible heat is an appreciable percentage of the total, and if this is removed by any means before gas reaches the burners such removal represents an absolute loss. On the other hand, hot gas can carry an enormous amount of water vapor and this moisture going through the system acts as a damper on the combustion and prevents the temperature from rising as high as it otherwise would. Therefore, to remove the moisture is in itself a benefit.

There has been a certain amount of misapprehension on this subject. There have been in recent months, two papers on the subject of gas cleaning, of which jointly the value probably exceeds anything published in England previous to that time. These are the papers of Mr. W. A. Forbes, "The Cleaning of the Blast Furnace Gas," before the October, 1913, meeting of the American Institute of Mining Engineers, and that of Mr. A. N. Diehl at the February, 1914, meeting of the same institute, entitled "Data Pertaining to the Gas Cleaning at the Duquesne Blast Furnaces."

From the former of these I shall presently quote extensively and from the latter also to a considerable extent, but both of these, in my judgment, give an erroneous idea as to the relative importance of removing moisture and of cooling gas. Table 2 of Mr. Diehl's paper is reproduced here as Table 1.

It will be seen that he gives calculations showing the amount of heat obtainable per cubic foot of gas under three conditions.

First—Washed and cooled to 70 deg. Fahr. and saturated at that temperature with water vapor.

Second—Washed and cooled 125 deg. Fahr. and saturated at that temperature.

Third—Unwashed at 400 deg. Fahr. and containing 35 grains of moisture per cubic foot; in other words, its natural condition as it comes from the furnace.

Three temperatures for the escaping products of combustion from the stack, 400 deg. Fahr., 500 deg. Fahr. and 600 deg. Fahr., are taken for each of the three cases.

Turning now to the third line from the bottom, "Total heat obtained per pound of dry gas consumed," it will be seen that the amounts in the three cases, all at 500 degrees stack temperature, are 1,076.6 British thermal units for the first, 1,088.43 for the second and 1,166.49 for the third. It is obvious that the most available heat is to be obtained with hot gas in spite of high content of moisture.

Mr. Diehl gives a percentage figure for the three cases in the second line from the bottom of 83.23 per cent, 78.4 per cent and 80.31 per cent. Based on these percentages he states that the dry cold gas gives the highest percentage of available heat.

This is obviously incorrect, as the highest percentage must plainly coincide with the largest absolute amount of heat obtained on any correct basis of figuring. The error has arisen by counting as available the latent heat of vaporization of the water vapor in the gas in all cases. But this is in fact not available under any known conditions of boiler or stove operation since it would require gases to be cooled far below 212 degrees to precipitate much of this moisture and recover its latent heat.

It is obvious that if the burnt gas comes in at 400 degrees and goes out of the stack at 400 degrees no loss whatever has occurred, while if it goes out at 500 degrees or 600 degrees, the only loss is that in superheating this small quantity of steam 35 grains, or 0.005 pounds of water vapor, with a specific heat of 0.48 through a range of 100 degrees or 200 degrees, making a loss per cubic foot of gas of only a fraction of one thermal unit.

In regard to the effect on the combustion temperature, the results are similar. The quantity of air required for combustion is about equal in weight to the gas itself, therefore the reduction of the initial temperature of the gas by a given amount results in a reduction of the temperature combustion by about one-half of that amount; to cool the gas from 400 deg. Fahr. down to 70 therefore reduces the theoretical combustion temperature by about 160 degrees. The removal of the moisture tends to raise the theoretical combustion temperature but quantitatively the amount of increase is smaller than the decrease due to the loss of sensible heat of the gas, about 100 degrees against 160 degrees.

When the gas comes from a furnace which does not work a wet burden of ore or wet fuel, the conditions become very much worse for wet scrubbing, because in that case there is but little moisture in the gas to be removed by a reduction of the temperature and therefore such reduction represents a net loss both of combustion temperature and of thermal efficiency due to lower combustion temperature.

In the discussion of the paper of Mr. Forbes above mentioned, it was stated by Mr. S. K. Varnes, of the

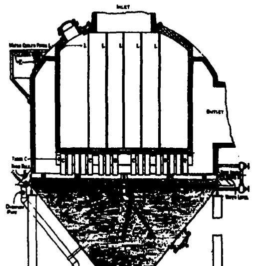

Fig. 4a.—Mullen gas washer.

Pennsylvania Steel Company, that at their furnaces they had introduced gas washers for the stoves but that they had been forced to abandon them because of the increased moisture and decreased temperature of the gas which resulted in a decided lowering of the combustion temperature and corresponding reduction of the blast temperature that could be obtained from the stoves. On the other hand, great benefit has been derived from wet scrubbing, where wet ore is used. Thus it will be seen that each case must be handled on its merits. Clean gas is always desirable, and undoubtedly much cleaner gas will be used in stoves and boilers than we have been accustomed to in the past, but wet scrubbing should only be adopted after the most careful analysis of the conditions to see whether the net results will be beneficial or not, and if so, to what extent. There is but little use in supplying stoves with clean gas and then finding that we can get from them only lower blast temperatures than we could with dirty gas.

(To be concluded.)

TABLE 1.—HEAT AVAILABLE PER POUND OF DRY BLAST-FURNACE GAS UNDER VARIOUS CONDITIONS OF INITIAL TEMPERATURE AND MOISTURE CONTENT. COMBUSTION AIR CONSTANT CONDITION.

Profits from Public Forests

THAT the public forests might be a valuable property for the community is pointed out by the Forest Service of the Department of Agriculture, which cites the case of the town forests of Baden-Baden, Germany, where scientific forestry is practiced. These forests yield a profit of $5.25 per acre, or a net revenue of $67,500 annually.

Hypnosis or Agony of Fear?

One of the subjects often discussed in the press, yet never settled is the question whether a snake can hypnotize a frog or bird so completely that it becomes helpless and allows the snake to seize and swallow it. The unlucky little creatures it is asserted, generally become rigid and unable to move at the sight of the enemy but in some cases they advance toward the snake as if drawn by some mysterious power and even spring right into its jaws. Once by way of determining whether a snake's eye really possesses this occult power the experiment was tried of pushing cautiously a board between the reptile and the frog hopping toward it. In a moment the spell was broken, the frog fled in joyous springs and the snake vanished into its hole. This seemed to be conclusive proof that the hypnotic state had been produced.

A somewhat different view of the matter is brought forward in the scientific notes of the German journal *Prometheus* by Herr Pfister of Rappoltsweiler. He is somewhat doubtful of the theory given above and asks how it is that such occurrences have never been observed among snakes in confinement. Or how it happens that rabbits and rats in a cage of snakes seem so unconstrained, nibble placidly and run around as though they had no suspicion of their impending fate? Rats have been known when driven by hunger to gnaw at the snake and even to eat it up altogether.

Our author's reasoning in maintaining his views is about as follows. It is certain that a human being can exert a strong influence upon another or can hypnotize him. As a rule this is nothing more than the power that a strong mind exercises over a weaker one, a forceful character over an undeveloped one. This can be observed any day in the case of a teacher in the school, of parents with their children, of a judge in the exercise of his office. A sharp look is often sufficient to break down the defiance of the wrongdoer. Among human beings this exercise of influence holds good, but how can the expressionless eye of a snake exert such a power over a frog, an animal so low in the scale of creation? An animal tamer can perhaps hold a lion or tiger within bounds by the power of his eye or rather by his daring demeanor. But let him try to exert this power over a frog!

The supposedly hypnotic cases continues Herr Pfister should more probably be attributed to the fact that animals are rigid with fright when they perceive an enemy just as men are when facing great danger. Moreover the frog like many other animals has the habit of simulating death in case of necessity until the danger is past. As snakes only attack living animals, in this way the frog is frequently able to save itself. If a frog should really hop toward a snake the probable explanation of this is that it does not suspect that the reptile lying motionless could be dangerous to it.

Our author explains the behavior of little birds at the sight of a snake in the same manner. No occult power drives a bird toward the enemy but its anxiety for its young. Whether the enemy be a snake, a cat, a marten or any other predatory animal, mother love leads the bird to forget its own danger entirely. Screaming with alarm it flits back and forth, strikes boldly at the enemy, seeking in every way to drive the intruder off, and often falls a sacrifice to its daring. There is no question of hypnosis in such a case.

Herr Pfister thinks we should be very cautious in accepting stories as to what people have observed, as imagination, the unusualness of the phenomenon, surprise and alarm often confuse the perceptions. Prof. Doflein in his work "The Animal as a Part of Universal Nature" says: "It has often been observed that birds upon the approach of a snake remain motionless as if under a spell. This was held to be a kind of hypnotic influence which it was asserted arose from the glistening of the snake's eye, from the sheen of its skin and from the uniform swaying back and forth of its head. According to others it was the sight of the snake which made birds stiff with fright. Investigations made at the Zoological Garden in London however led to an entirely different result. No species of animal with exception of the ape looks upon the snake as something to be feared and exhibits signs of terror at the sight of it. Many animals show rather something like curiosity and look at a striking object with great attention but without moving, whether the object be a snake, a ribbon or a human finger. If therefore the snake throws itself quickly at the right moment on its prey the victim is caught and this without any magic."

The same opinion is also reached by Dr. Kurt Floericke in his work "Reptilia and Batrachia of Germany." He says: "The spell of fascination exercised by the snake's eye whereby the victim is said to be held in a measure to one spot in order thus to fall a more easy prey should at the present day be regarded as an exploded theory."

Our author quotes further Brehm's "Animal Life," which simply gives all the cases which the writer has been able to draw from reliable sources without expressing a positive opinion one way or the other, while Prof. Doflein calls any such story an interesting scientific fable without actual basis.

The Lightest Known Wood

When one sees and handles for the first time a piece of the wood of the ambach or ambatscha tree he immediately conceives the idea that the material would serve as an admirable substitute for cork. Upon inquiry he soon learns that all woods which are characterized by a very low specific gravity and softness have been used only to a very limited extent in place of cork because all of the so-called cork woods known to man do not possess the high elasticity, impermeability and durability peculiar to cork. With the single exception of cork wood or balsa (*Ochroma lagopus*) of tropical America, which is used for making life preservers, these soft, light and pith like woods rarely enter the markets. Their uses are for the most part confined to carving and ornamental work in the countries where the plants are native. The adaptation of shola or sola (*Aeschynomene aspera*), a remarkably soft light wood used in the manufacture of shola hats, is perhaps one of the principal exceptions to the rule. The shola tree is found growing in India and Ceylon, where it is used extensively for making hats out of the spongy substance developed on the stems when growing in the water as they generally do. These hats are of remarkable lightness and are well adapted to the climate as they are poor conductors of heat. The wood is employed also in many parts of India and occasionally in England and to a lesser extent in the United States for fishing floats, models and for an infinite variety of ornamental purposes. Latterly however shola and other similar soft woods have been applied for the packing of machinery bearings.

Ambach, upon which experiments have been made for this and other purposes, is a leguminous plant known to botanists as *Herminiera elaphoxylon*, a native to the Nile and Lake Chad regions. It is called ambach or ambatscha in the region where it grows and the wood has attracted considerable attention under the names of ambach and tripol, the latter name is probably derived from the name of the town or region from which the wood is principally shipped. The English speaking people along the Nile call it pith tree because the wood resembles the pith of elder or of other trees having a very light pithy center. The tree grows to a good size, forming tolerably thick trunks, and is of very rapid growth. It is said to attain a diameter of 6 inches in two to three years when it dies and another young tree springs up from the same underground parts. The growth of these plants is so rapid and occurs in such great abundance that it frequently chokes up the channels of the numerous tributaries of the upper Nile. The wood is remarkable for its very soft texture and its appearance of a mass of pith. It is exceedingly light in weight, brittle and is nearly white when it is cut but turns slightly darker upon exposure to light and air.

Ambach is the lightest wood in existence. A sample of balsa from Trinidad exhibited at Philadelphia in 1876 had a specific gravity of 0.120 or about seven and one half pounds per cubic foot. The specific gravity of common cork (the bark of *Quercus suber*) is given by Ganot as 0.240. There are no figures extant on the specific gravity of ambach but on an average it is much lighter than either balsa wood or cork. Owing to its extreme lightness the natives use it to assist them in swimming across the rivers. It has also been used by the natives in Africa for making hats and floats and has occasionally been shipped to England and the United States for making floats for fishing tackle and as a substitute for cork. It has been found to split too easily under radial tangential pressure and it is soon water soaked and cannot be used successfully for the purposes for which ordinary cork is now employed.

Although ambach is very soft it has been found that it cannot be used for such purposes as packing machinery bearings and delicate instruments, because it tends to wear away the metal where it rests on the wood, which contains numerous minute crystals of calcium oxalate. These crystals have also a great deal to do with the dulling of tools used in cutting the wood. These qualities are recommendations for the use of this wood as razor strops for which it has been employed successfully for a good many years. The woody tissue of the flowering stems of the American aloe (*Agave americana*) is often cut and shaped by the people in the country where the aloe grows into the form of strops and there is no doubt of its efficiency for this purpose. The wood of ambach is more compact, even grained, and apparently more durable and serviceable than the aloe.

Locating Metals in Wounds

It is often difficult to locate bits of metal in wounds, such as rifle bullets, fragments of shells or shrapnel and the suggestion has been made that the Hughes induction balance can be of great use for the purpose. The balance consists of a battery and interrupter, in series with two primary coils, on which are wound secondary coils connected in series with a telephone, the leads are crossed, and the coils are exactly alike, so that normally their effects are exactly neutralized, and no sound is heard in the telephone. When, however, a metallic body is placed near one of the coils, the eddy currents induced in the metal react upon the coil and disturb the balance, so that a sound is heard in the telephone. When the metal is magnetic, as in the case of splinters of shell or bullets, the effect is much increased. Thus the device can be used to indicate the presence and to some extent the nature, of a metallic body, and its approximate position.

SCIENTIFIC AMERICAN SUPPLEMENT

Founded 1876

NEW YORK, SATURDAY, FEBRUARY 6, 1915

Published weekly by Munn & Company Incorporated
Charles Allen Munn, President; Frederick Converse Beach, Secretary; Orson D. Munn, Treasurer
all at 361 Broadway, New York

Entered at Post Office of New York, N. Y., as Second Class Matter

The Scientific American Publications

Scientific American Supplement (established 1876) per year $5.00
Scientific American (established 1845) 3.00
American Homes and Gardens 3.00

The combined subscription rates and rates to foreign countries, including Canada, will be furnished upon application.
Remit by postal or express money order, bank draft or check.

Munn & Co., Inc., 361 Broadway, New York

The purpose of the Supplement is to publish the more important announcements of distinguished technologists, to digest significant articles that appear in European publications, and altogether to reflect the most advanced thought in science and industry throughout the world.

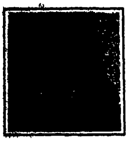
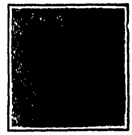
VOLUME LXXIX NUMBER [illegible] NEW YORK, FEBRUARY 13, 1915 [10 CENTS A COPY $5.00 A YEAR

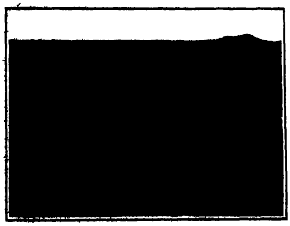


A Votive axe in pottery

A panoramic view of the excavated area in the north of the Royal City

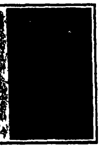


Bronze scepter head.

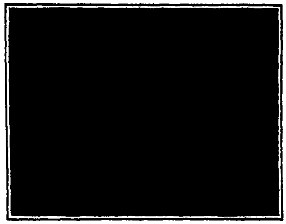


Shrine of the Royal City a short distance outside the walls to the south showing the two stelae, or tablets bearing inscriptions, which are believed to be the best continuous Ethiopian inscriptions yet discovered.

A wooden model illustrating the plan of the sun temple with the fore part as a sun-dial

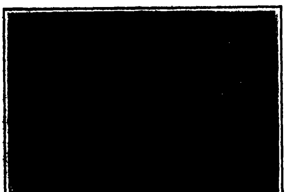


A cameo of onyx with galloping horses to represent day and night—Greek of B C 250

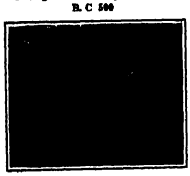


Observatory showing two observation stones and wall of graffiti and steps to tank. The baths in the tank are shown in another illustration. Meroë will soon be covered by the waters from the Assouan dam.

Fittings from the royal throne—B. C 500

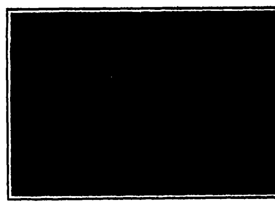


A bath in observatory building (Plan showing locations of baths.)

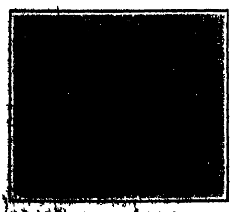


An altar with a fetish

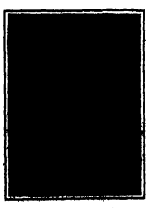
A stone recording observed angles.



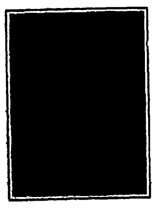
A bath recently discovered in the street leading into the palm court



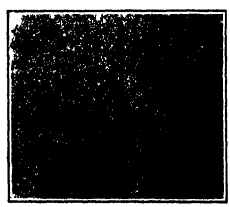
An [illegible] on the wall of the observatory [illegible]: An astronomer [illegible] instruments.



Great Stela inscribed with 42 lines of Meroitic writing that has not been deciphered.



A graffitto giving astronomical calculations and a record of observations.



Records and calculations on the walls of the observatory

A diagram of the stone for recording observed angles.

An ancient centre of astronomical science.

MEROË, THE ROYAL CITY OF ETHIOPIA.—[See page 98.]

Meroë the Royal City of Ethiopia

Important Discoveries that Indicate Advanced Knowledge of Arts and Sciences

LOCATED on the River Nile in southern Nubia the region of Ethiopia of olden times was the city of Meroë which has long been the scene of much archaeological investigations as it has yielded many antiquities that have thrown much light on the history of forgotten races and nations and their foreign relations and influences (at first Egyptian then Hellenistic-Greek and subsequently Roman with reason to believe that evidences of still other races will be discovered) which dominated their development During the past season valuable discoveries were made which were described in the *London Illustrated News* by Prof John Garstang of the Institute of Archaeology at the University of Liverpool and many of the objects recovered that were exhibited in London were illustrated in the above publication from which our illustrations and information are derived

These objects illustrate the character of Ethiopian culture from the establishment of the court at Meroë in the sixth century B C to the destruction of the city in the third century A D but one of the most important results of the explorations has been the proof that the city of Meroë was a center of astronomical science of no small importance The description by Prof Garstang of the discoveries is as follows

The season 1914 has advanced our work in the royal city at Meroë to a penultimate phase We have now been able to connect up the various areas in which we have been excavating for some years and to uncover completely the northwestern corner so that the whole of the northern portion of the city has now been brought to view It only remains to uncover and enclose the southern portion to bring the excavation of this central feature of the site to completion The Sudan Government has already instituted a convenient service of trains and accommodation for visiting this ancient capital of the country

The buildings of the later portions of the Middle Meroitic period (circa B C 150) reveal the city at its prime The main entrance through the northern wall led on through an avenue of trees towards the center of the city where on the left hand or eastern side there seems to have stood a public building fronting or replacing the now time-honored portico which had stood there it would seem in the sixth or seventh century B C Almost opposite was an indefined building of solid foundation which to judge from the records of observation and calculation found along its western side may indeed at that time have been an observatory and residence of an astronomer The palace of these times lay immediately to the left of the main gateway a large building with central courtyard and veranda Opposite the palace in this quarter is the enclosure which seems to have been walled off as a place for interring the cremated dead The crematorium itself has been found in the building at the head of the street last mentioned the flues and hearth still remain, and the floor was found littered deep with partly incinerated bones

While the development of the general plan has not been without its measure of surprises, it has nevertheless much simplified and amplified our provisional chronology The fact that the early gateway and the secondary gateway through the northern wall were obviously in contemporary use being linked together by the palace of Netog Amon and the road-system around this building, led us *inter alia* to the inevitable conclusion that the main city wall was built at the beginning of our Hellenistic Period in the early third century B C Some buildings thus pre-existed the main city wall which was only raised around the area some centuries after these had been built

There is evidence to show not only that there was a place and equipment for astronomical observations at Meroë in the second century B C but also that it was in close proximity to this building for on what was then the outside western wall we found a number of graffiti representing both calculations or record of observations and actual sketches of two instruments which would seem so far as they can be understood to correspond to a transit instrument with circle and an azimuth instrument

A special flight of steps subsequently disused seems to have led down from that side of the building to the outer level where these graffiti and other features are to be found The other material evidence consists in the remains of two columns or pedestals One of these columns is hexagonal the other square The latter is carefully set upon a stone plinth in such fashion that certain markings on its side correspond exactly to marks upon the base and the alignment is controlled It would seem from a sighting point upon the further side of the hexagonal column This alignment is still true and its bearing east of magnetic north is 128½ degrees The magnetic deviation lies probably between 2¼ degrees and 3 degrees west at the present time

Upon the face of the square column which is turned towards the other that is its western face, there are engraved three lines which if produced upwards would meet more or less accurately in a point The outer lines converge upon the middle line so as to make angles in each case of approximately 14 degrees The middle line is not (at the present time at any rate) truly vertical but is inclined at an angle of approximately 3¼ degrees the bottom of the line being to the south of the point vertically below the point of intersection of the three lines in question This face of the stone is not set in the meridian nor is it quite true in its own plane Its bearing along the bottom is 37½ degrees east and along the top 40½ degrees There is a possibility of error in our record of these details amounting to about ± ½ degrees

We have thought it best to publish these bare facts because astronomers everywhere cannot fail to be interested in the obvious significance not only of this diagram but of the calculations and the designs upon the wall

The latitude and longitude of Meroë, determined 5 years ago are 16 degrees 56 feet 18 inches North, 33 degrees 44 feet 18 inches East, and it will be noticed at once that the inclination of the southernmost of the three lines to the vertical upon the square column almost corresponds with the latitude.

There are many interesting records in the pages of Pliny, and some in other writers, all tending to show that the astronomers of the second and third centuries B. C. made consistent observations at various points in and about the Nile basin with a view to determining latitude and other astronomical data. It is related, suggestively, that at Ptolemais, which was on the Red Sea coast, very nearly in the latitude of Meroë, an interval of 45 days elapsed between the summer solstice and the two days (before and after) whereon the shadows of the sun were vertical at noon (Pliny's 'Natural History,' II., 75—VI., 34) Now the graffiti of the wall include the calculation or record of a series of observations which will be seen to involve the number of forty-five on each side of an equation with a difference at the foot on one side of three, and on the other side of ten. This summation of figures is represented in units arranged in five groups of three and in three lines in each case, and it is obviously suggested that it is really the record of observations kept daily and that 45 days on each side was the basis of calculation Pliny tells us, significantly, that at Ptolemais which is approximately on the same latitude as Meroë, the shadow of the sun was vertical *45 days before and after* the summer solstice.

There is another significant feature about the position of these astronomical monuments, for we are told that when at the end of the third century B C Eratosthenes determined the latitude of Assouan and the size of the earth, he made use of a deep well for the purpose of his observations The date of our monuments is, however, more nearly that of Hipparchus, who is credited with many improvements and additions to astronomical instruments

Outside the city we made further experimental examination of three spots, including a number of prominent mounds located along the south side of the Temple of Amon

One other site was examined, an isolated mound lying some 2 or 3 kilometers to the south, not far from the village of Hamadab The most immediate result was the discovery of two great stelae, inscribed in Meroitic cursive characters both apparently historical narratives. A few hours work showed the important nature of the inscriptions

The two stelae are of the characteristic dark grit used anciently in this locality for special purposes, such as altars steps, thresholds, and the like They were found left and right of the entrance to the shrine mentioned facing outwards towards the west The larger and more perfect inscription was on the left (or north side) The stone itself is 2.58 meters in height, with a maximum width of 1 10 meters, and weighs 3½ tons The inscription fills 42 completed lines, 4 lines at the bottom being blank, covering a height of 141 centimeters below the sculptures on the dressed face of the stone

The Engineer in the Field

THE Marquis of Graham delivered his presidential address recently before the Junior Institution of Engineers Sir Boverton Redwood Bt in the chair He took as his text, 'The War and Engineering' and remarked that war had become very largely a matter of engineering If Attila's army of 700 000 Huns were excepted no warrior had hitherto had more than 60 000 troops to transport, maneuver and maintain The Kaiser to-day boasted his four or five millions of all arms The Allies had legions equally numerous, and from each of the farthest ends of the world Britons had come in great convoys of steam transports, which dwarfed in significance the armadas of Athens, Carthage, and Rome and England of old

Referring to the movements of the British Expeditionary Forces by rail and steamship Lord Graham said that the government required the British railways to collect from all parts—north south east, and west—troops whose numbers and impediments needed 350 trains made up on an average of thirty vehicles each, and to detrain them at the ports of embarkation within forty-eight hours. This great feat was accomplished. As was now well known, most of the troops left from Southampton and for weeks trains were passed over the lines during the night at the rate of five trains per hour Such a performance was not only creditable to the organization of the railways, but proved that the mechanical equipments and direction of the port were most efficient. To tackle the troops, horses, guns, limbers, and other accessories of battalions arriving in seventy three trains within fourteen hours on successive nights was an unprecedented feat. It was right, however that similar credit should be given to the harbor authorities at Marseilles, where twenty-eight vessels with our Indian troops and their munitions of war were dealt with in twenty four hours Remarkable work too had been done by the Russian railway authorities

Motor vehicles played a great part, secretly and silently in the transfer of the British army from their trenches 100 yards in front of the enemy on the slopes in the Aisne Valley, during the night of October 20, to the new battle front on the Yser Such an unexcelled strategic movement by a great army would have been almost impossible without motor conveyances in addition to railways

Great improvements had been made in guns, and the rate of fire was at least 100 times faster than of old. The German 16½-inch howitzer, firing a 1¼-ton shell, was, for transport purposes, taken apart to make four separate loads, and none of these, including the cylinder, weighed more than [illegible] tons. Each was hauled by three road tractors, with reserves for supplementing the tractive effort through cables and drums on inclines or hilly ground.

In the first six weeks of the war British aeroplanes flew an average distance of 2,000 miles a day, and nothing was hidden from the observer in the flying machine. For instance, an airman at an altitude of [illegible] feet above London could, if the weather conditions were favorable, see the whole coast line from [illegible] to Yarmouth, and see even the shore cliffs of France beyond.—*The Daily Telegraph.*

Monorail Electric Cranes

OF late the European electrical industry is furnishing an interesting type of monorail crane, as it is called, in the shape of an electric carriage traveling upon a structural iron beam. Such a construction will often be most convenient, especially upon building sites or within works, where space is limited and materials need to be handled rapidly over considerable distances. The Oerlikon monorail carriages run suspended from the lower web of an I beam or a pair of assembled channel bars. Such a crane will answer for unloading railroad cars and it takes the place of small surface cars with the advantage that no rails on the ground or [illegible] are needed. To the carriage is fixed an iron frame support with seat for the operator, who works the controllers for the main motor and for the lift motor. Translation of the carriage can also be done by hand. [illegible] be noticed is that the lift motor drives the [illegible] by the recently introduced [illegible] method which we described previously [illegible] advantage of [illegible] [illegible] since its introduction [illegible] method has proved [illegible] in this [illegible]

Wireless Telegraphy*

A Review of Some Notable Developments of the Past Year

When Sir Ernest Shackleton left England in October with the object of crossing the Antarctic continent from the Weddle Sea to the Ross Sea, he took with him a wireless telegraph station having a range of about 500 miles. Apparently it is not Sir Ernest's intention to use wireless telegraphy on his ship, but there is no doubt that it will be a valuable resource to members of the sledge party in enabling them to communicate with the base. Early in the year it was announced that the Postmaster-General had consented to a license being granted to Marconi's Poldhu station for the purpose of conducting a commercial wireless telegraph service between England and Spain. In January wireless telegraphy played an important part in the saving of life at sea, but for reasons of space we cannot do more than make a passing mention of one notable instance—that of R.M.S. Colequid which went ashore on the Trinity ledges in the Bay of Fundy. If the vessel had been unable to send out its appeal for help far and wide all on board would have been lost, for even as it was it was not easy to find the wreck in the midst of the wintry storm in a bay where the rise and fall of the tide is greatest, perhaps, than in any other part of the world, amounting to between 60 feet and 70 feet. But for wireless telegraphy it is undeniable that the situation would have been hopeless.

When the new chain of wireless stations now in course of construction by the Canadian government is finished and in operation, it will be possible for a passenger on any incoming steamship to communicate from mid ocean as far inland as Fort William. All down the river and gulf the government stations are in regular operation.

The Marconi Company has been engaged for some time in the design of wireless telegraphy for air craft and during the past year experiments were carried out at Hendon, and there is good reason to believe that the Marconi apparatus in its latest stage of evolution will meet the demands of naval and military authorities.

Finisterre, Santander, and Cape Palos must now be marked on the map of the world with a sign that denotes the existence of a wireless station. All three stations have now been in working order for some time and have been subjected to exhaustive tests by a commission appointed by the Director-General of Spanish Posts and Telegraphs. In March it was reported that the Admiralty had accepted a tender for an important extension of the naval wireless station which is situated on Horsea Island in the upper reaches of Portsmouth Harbor. Originally the aerials were 180 feet high but they are to be replaced by 400 foot aerials and the electric installation will also be improved enabling communication to be established with all parts of the Mediterranean.

In reviewing progress in 1913 we referred to some wireless telegraphy experiments made on moving trains on the Delaware, Lackawanna and Western Railroad. Further tests were made during the past year tests which demonstrated the efficiency of the Marconi system without a doubt. The railway company has completed a steel tower 402 feet high on the water front at Hoboken and has installed a 5-kilowatt high frequency set at this point. On September 19th wireless messages were received from Hoboken at the Lackawanna wireless station at Buffalo a distance of 410 miles on a wave length of 2,250 meters. A regular wireless service will shortly be commenced. The example of the Postmaster-General in deciding to substitute wireless telegraphy for the existing overland wires in exposed parts of the United Kingdom is to be followed by the government of the Commonwealth of Australia, so as to bring outlying country districts into permanent communication with all the towns and business centers. Twelve wireless installations have been established in the country districts of Queensland and New South Wales. The federal government has also decided to employ wireless telegraphy as an aid to the construction of the trans-continental railroad and to assist the operation of trains.

In answer to a question in the House of Commons on May 13th the Postmaster-General made the following interesting announcement: "A successful demonstration of wireless telegraphy at 100 words a minute was recently given by the Marconi Company between Chelmsford and Letterfrack (Galway) and it is proposed to adopt this method of working between a station which I am about to establish near Stonehaven and an existing post-office station near Newcastle-on Tyne as a stand-by in the case of the interruption of the overhead lines. High-speed transmission and reception is rapidly becoming essential to the efficient working of commercial wireless telegraph stations. By the use of such a system several telegraphists can be employed in punching the tape to feed one transmitter and thus all messages can be got through without delay and the traffic capacity of a station can be increased many times."

Although Great Britain has hitherto taken no very prominent part in the organization and maintenance of an international time service there are signs that the subject is beginning to arouse some public attention. Mr. Charles Bathurst asked a number of questions in the House of Commons on April 21st with a view of eliciting information. He pointed out that as a result of the International Conference on wireless time signals which took place in Paris in October 1912 a preliminary list of high power wireless stations organized to transmit time signals at stated hours had been issued. Although this list contained stations in every part of the world it contained no station in any part of the British Empire. Mr. Churchill who replied admitted the facts were as stated by Mr. Bathurst but he added: "the British delegates at the conference made certain recommendations for the establishment of time signals at wireless stations in the dominions and colonies which would have the effect of greatly increasing the value of the scheme and I understand that these recommendations have been brought to the notice of the governments concerned." The report of the Astronomer Royal for Scotland refers to the new receiving time-signal apparatus which during the session 1913-14 was added to the equipment of the Edinburgh Observatory.

Considerable attention was paid during the year to the controlling of mechanisms from a distance solely by the aid of electric waves. Several articles dealing with this subject appeared in the *Wireless World* one of the most interesting being on remote-controlled fog signals installed in the Firth of Clyde. With the opening of a new station at Kingston a new link was formed in the Canadian wireless chain. This station which was built by the Canadian Marconi Company, is a standard 5.5-kilowatt station. Bombay like all principal ports in the world is now fully served with wireless telegraphy equipment to meet present requirements and this has been demonstrated in the work that has been carried out at the new wireless station on Butcher Island.

The new wireless station at Carnarvon in North Wales for communication with New Jersey U.S.A. has now been completed some time and the American station or rather stations for the system employed is duplex and the transmitting and receiving stations are some distance apart—was also finished during the past year. The plant at the New Jersey stations is practically identical with that at the Welsh stations.

Farmers residing in the isolated districts of Australia have long been handicapped by the lack of means of swift communication with the outside world. Far from towns they are often compelled to put up with inconvenience and dangerous delay in the satisfying of wants and necessities. An interesting suggestion for a remedy for this state of affairs has been made by Mr. W. King Witt vice-president of the Wireless Institute of Victoria who has pointed out that the terrors and disadvantages of loneliness might be greatly reduced by the use of wireless telegraphy.

An important link in the trans-Pacific wireless chain was formed with the opening of the Marconi high power wireless stations at San Francisco and Honolulu. This is an event of world wide importance signaling as it does a further advance in the commercial development of wireless telegraphy by bringing that means of communication within range of a considerably increased number of users of the world's telegraphs to whom the reduction of cost which the wireless service makes possible in addition to its other advantages is a matter of no small moment. According to the latest Australian newspapers the authorities are making arrangements for big improvements at the different lighthouses around the coasts of Australia and new lighthouses are to be provided where necessary. The question of communication with the shore is also under consideration, and it is reported that in this connection a low power wireless system will probably come into operation. In the army and in the navy wireless telegraphy now plays an important part and is being used very extensively in the present war. Naturally this brief review only covers some of the most important developments during the past year. Wireless telegraphy advances very rapidly and a complete survey of twelve months progress would occupy far more space than we can spare.

A Practical Fertiliser for Wartime in Germany

In the last analysis a man's ability to fight depends on the quality and quantity of his food, and these depend, if his country is blockaded against supplies from elsewhere, on the quality and quantity of the crops that can be raised at home. But of all the factors that determine the latter, that of the proper fertiliser, or plant-food, is the weightiest.

Small wonder, then, that German agriculturists, cut off from the customary supplies of Chili saltpeter, should be considering this question anxiously.

A writer in a recent number of the German journal devoted to the interests of the oxygen and nitrogen industries, *Zeitschrift für Sauer und Stickstoff Industrie*, discusses the question to much purpose. He points out that the chief fertilisers generally employed, besides [illegible], are Chili saltpeter and sulphate of ammonia, while the artificial substitutes, nitrate of lime and [illegible], compose only 5 to 10 per cent [illegible].

[illegible] the chief source of sulphate [illegible], there can be no lack [illegible] in price, because of [illegible]. But the writer has [illegible] the Haber process [illegible] on the market [illegible] to such an [illegible] sible use of other sources and to collect those fertilisers which are readily obtainable in Germany and apply them in time to prevent a reduced harvest next year.

At his instigation Herr Julius Woldering of the *Ritter gut Jocksdorf* has been conducting practical experiments with a fertiliser composed of finely ground calcium carbonate and coal or pulverised coke with excellent results. He says:

An addition of about 20 per cent of fine sifted coal or coke in most cases is a good substitute for Chili saltpeter, and is, at least for a like yield considerably cheaper than all other mineral chemicals. This fertiliser of lime and pulverised coal has given extraordinary results with rye, oats, potatoes, peas, and beans. He advises that the mixture be used in stables in the winter as an underlay for the straw, in order to absorb the highly valuable nitrogenous fluids. This forms an excellent meadow fertiliser.

A very great advantage of this fertiliser is the fact that the raw materials can be hauled in wagons and mixed by the farmer himself. In localities where large quantities of sulphite lye from cellulose factories can be obtained it makes an admirable addition to the manure, but such addition requires a special method of handling, which the farmer will have trouble in doing for himself. He estimates that the cost of this lime-coal fertiliser is only 5 per cent of that of Chili saltpeter.

The crop yield is, according to the above-mentioned [illegible] equal to that [illegible] the usual mineral fertilisers. He also finds that the crop is sounder than that produced by Chili saltpeter which forces the growth too much. Another important feature is that the addition of carbon to the soil compensates for the gradual depletion of this element by the steady sale of the greater part of the straw each year. Also a large part of the straw used for bedding can be dispensed with. He closes by urging German agriculturists to profit by this new cheap fertiliser whose value has been conclusively proved by the scientific researches of Dr. Fischer and Dr. Bornemann.

Encouraging Tree Planting

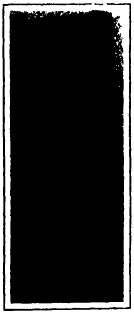
The Massachusetts Forestry Association is making some very practical and well-directed efforts in the way of interesting towns within the sphere of its activities to undertake the work of tree planting systematically by offering a series of prizes. In four classes of towns, designated on a population basis, which win prizes for excellence in street tree planting the association will plant one hundred additional shade trees, which should be a strong inducement to any community that takes a proper pride in the appearance of its streets. The association is also encouraging town forests, and for the town that takes the first place in this work the association will award a prize in the form of fifty acres of white pine to be planted free of cost by the association. These are good suggestions that might be adopted by associations in other States.

Making Safe Steel Rails

A New Process Intended to Meet Modern Railroad Requirements

An authority on railroad matters has stated that 90 per cent of the rail failures can be divided into two general classes first crushed and split heads, and second broken bases The former are caused by excessive segregation producing brittleness in the interior of the section and the latter can usually be traced to a seam in the bottom of the base Fifty per cent of the rail problem consists in getting sound metal of even composition and 40 per cent consists in so rolling the steel as to avoid seams in the base"

These conditions have of course made themselves



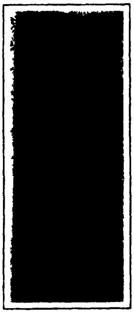


Fig 1.—Face of an ingot before heating Fig 2 —After heating, adhering scale removed

felt only since the weights that the rails have to sustain have increased to their present proportions and it is evident that the art of rail making has not kept up with the progress in railroad development in other directions for the facts show that merely increasing the weight of the rail does not enable it to meet the increasing demands that are being made on it If proof of this were necessary it could be furnished by the record of one road which had 2 700 rail failures during the three winter months of 1911 12 and the fact that rail failures are rapidly increasing in this country The conditions and the reasons have been recognized and attention has been called to the fact that chemical analysis of a test ingot does not furnish assurance of the condition of the finished rail and that the specifications governing the acceptance of rails are entirely inadequate

Why this state of affairs should exist is difficult to say even while recognizing the difficulties that confront the rail maker but it is gratifying to see that at least one concern is taking active steps in seeking a remedy as described in the following paper read by Mr Robert W Hunt before the American Society of Mechanical Engineers which is here reproduced from the *Iron Age*, but it may be noted that one of those who discussed this paper made the very direct suggestion that the remedy cured something that ought not to exist

Increased weight of rolling stock and speed of traffic have necessitated increasing the size of the rail sections, and hence their weight, and as many of the details of rail manufacture have been changed with such alterations, it is not surprising that new and unexpected physical weaknesses developed in the heavier rails One of the most notable was failure through crescent-shaped pieces breaking out of the rail flanges followed by at least one, and in many cases several ruptures across the whole section of the rail Investigation showed that in practically every instance of such failure there was a more or less pronounced seam running longitudinally in the bottom of the rail near its center and thus immediately under its web This seam occurs at the top of the curve of the crescent-shaped break and it is undoubtedly the point at which the fracture starts

It is true that rails with actual flaws in their flanges have been rejected as first quality ones and that a very pronounced seamy condition of the bottom of the rail would also cause its rejection Such rejections were the cause of frequent disputes between the mill operatives and the inspectors the point being as to how far the inspectors were warranted in carrying their condemnation but as already said it was not felt that a single seam unless very pronounced would be dangerous

The crescent-shaped breaks were of such frequent occurrence that they indicated a very serious condition and led rail makers to experiment with the design of their rolling passes with a view to obviating the formation of the bottom seams It was found that fewer seams were produced by such changes but they were not entirely eliminated While more or less successful in preventing the formation of seams through lapping on the bottom of the rails the formation of seams in other parts of the section was not particularly affected

T H Mathias assistant general superintendent of the Lackawanna Steel Company determined that the most certain way of getting rid of seams was to remove that portion of the metal which contained them and as applied to steel rails thus to eliminate them from both the base and head of the rail This was a reasonable assumption but its execution I think would have seemed very impractical to most metallurgical engineers Mr Mathias reasoned that the primary causes of seams existed previous to any rolling of the steel in fact were incident to the casting of the molten metal into ingots He knew that disk-like apertures were formed on the sides of ingots while the molten metal was being cast and were probably caused from air being entrapped against the sides of the ingot molds by the hot steel as it rose in the molds a condition which was not controlled in regular manufacturing routine This condition is illustrated by Figs 1 and 2 which are photographs of the same face of an ingot Fig 1 showing the side as it would appear before heating while Fig 2 shows it after heating with the adhering scale removed Fig 3 represents the actual size of a section of a face of such an ingot, and gives an illustration of how serious such apertures may be It will be appreciated that, as the section of the ingot is reduced and elongated in the rolling process, so, of course, will the apertures be stretched longitudinally and thus be formed into seams.

Mr Mathias demonstrated that there is another constant condition present in the rolling of large steel ingots, in the formation of a decarburized surface on all of their four faces about 5/16 inches deep, and containing from 8 to 10 points lower carbon than the metal immediately under it, the decarburized envelope undoubtedly being produced through the oxidizing conditions to which ingots are subjected in the soaking pits where they are heated preparatory to rolling A thick oxide scale is always formed on the surface of ingots in the pits, so that conditions are invariably present for the production of such

Fig 3 —The milling tool

a layer of lower carbon metal on their outside faces. Fig 4 illustrates the presence of this lower carbon envelope or skin It shows a polished and etched cross-section of a part of an ingot which has been heated to a rolling temperature in the soaking pits but not rolled, from which it will be realized that ingots of large section have both disk-like apertures on their four faces and a decarburized envelope in which they are contained.

Mr Mathias was convinced that during the process of rolling ingots into rails it was practical to remove mechanically the parts of the enveloping steel which would form the top of the head and bottom of the flange of the rail and experimented accordingly He designed and his company installed as an addition to their rail train, a milling or a hot sawing machine, as I believe Mr Mathias designates it to cut off hot metal without retarding the regular operation or thus interfering with the production of the mill This is illustrated by Fig 5 which is a photograph of the machine in operation. The machine is located in echelon in relation to the rest of the rail train.

The ingot is reduced in the blooming rolls to an 8 by 8 inch cross-section and after cropping the ends the bloom is further reduced in the roughing or shaping stand of rolls by five passes When it leaves these rolls, it is approximately 75 per cent finished and at this period it is carried to the right and entered between two pinch rolls with its base or flange side up A bar which will make four 33-feet rails is at this point in the rolling operation about 60 feet in length, therefore, the area of metal to be cut off or removed in the milling machine is approximately ⅛ inch deep, 7 inches wide and 60 feet long It is driven through the pinch rolls at a rate of 60 feet in 30 seconds The pinch rolls have a draught of about ⅛ inch and thus force the bar between the two milling saws, which are so arranged in the housing that they may be raised or lowered as desired From 1/32 to 3/64 inch of metal is milled from the head and base of the bar, the front end of which, immediately on passing from between the rolls, is caught by a second set of pinch rolls which have a draught of about 3/16 inch. These pinch rolls force the bar between the tools, pull it from between them, and also hold it in practically perfect line for the milling operation. The milling apparatus is driven electrically and requires about [illegible] horse-power for its operation.

Fig. 6 shows an etched cross-section of the [illegible] preparatory to its entering the milling machine, and [illegible] it is clearly shown the enveloping layer of [illegible] steel.

As the [illegible]

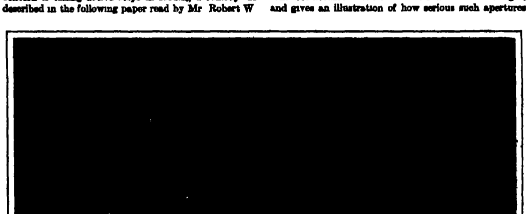

Fig. 5.—Hot sawing or milling machine in operation.

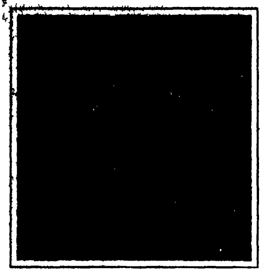

Fig 3.—Section of face of ingot, full size

7 shows the condition of the accumulated material which is in regular open hearth furnace charging boxes

Fig 8 shows one of the milling tools It is 5 feet in diameter with an 8-inch width of face and revolves at a peripheral speed of 2 500 feet per minute thus causing an engagement of about 400 000 teeth per minute on the hot rail bar The teeth are of 0 80 carbon steel and it has been demonstrated that they will mill at least 30 000 tons of material without requiring dressing The one shown had milled about 15 000 tons

Fig 9 presents the shape of the bar after it leaves the milling machine preparatory to further reduction in the regular rail rolls It will be noticed that the milling on the flange has not reached the extreme edges of the bar and on the head side has not affected the corners, and it will be recalled that Fig 8 showed the milling tool with a straight face It is apparent that either by a modification of the shape of the piece as presented for treatment in the milling machine or what will probably be more practical changing the face of

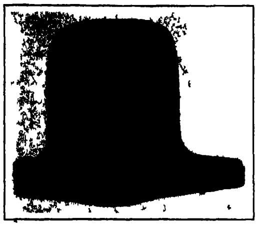

Fig 6 —Cross section of bar before entering machine

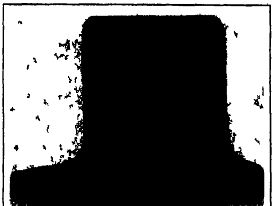

Fig 9 —The bar after it leaves milling machine

the tool the milling can be extended to the extreme edge of the flange portion of the bar and somewhat around the corners of the top or head side This will undoubtedly be perfectly practical and thereby eliminate the seams which may be located in these parts of the bar Such elimination is not accomplished at present and perhaps it may not be necessary The primary object was to eliminate the seams from the central portion of the bottom of the rail which had been the starting point of the moonshaped failures and to remove them from the top or bearing surface of the head of the rail Personally I think it will be desirable to extend the milling by the use of concave-faced tools

The work of rolling which the steel receives after the removal of the more or less laminated metal must produce a better product than if such elimination had not taken place and in the case of steel rails it should not only make them less liable to breakage on account of seams in their flanges but also enable them better to resist the abrasive effects of traffic

During the many years of my connection with rail making I have examined a great many etched specimens of rails not only directly in connection with the process under consideration but for various other reasons From such experience I can fully appreciate what Mr Mathias has accomplished The surfaces of practically all rails when etched will show some seams on both base and head and very frequently the extent of such defects will not be appreciable if the scale has not been removed Even then it is not always an easy or certain matter to estimate the depth of the seams When the rails have been subjected to the Mathias milling operation and still show pronounced seams it has been found that breaking tests will practically always develop the fact that the suspicious marking is an actual seam

To illustrate the appearance of many ordinary steel

Fig 4 —Etched surface showing lower carbon skin of ingot

rails of commerce when etched Figs 10 and 11 show the surfaces of both heads and flanges These specimens were taken from rails made by several different makers, including the Lackawanna Steel Company These illustrations not only clearly show the field for such an operation as I have described but also the extent to which Mr Mathias has been able to accomplish it

While I have confined myself to the matter of steel rails it is patent that the process will be of great value in the preparation of blooms for axles and all other kinds of forgings As is well known it is practically the universal custom to endeavor to remove the seams developed in rolling axle billets by chipping them out through the use of pneumatic hammers and for some of the higher characters of forgings notably for automobile parts, the endeavor to eliminate the seams is carried to the extent of turning off the whole surface of the billets. I am confident that by the Mathias plan the greater part if not all of such work can be superseded

Waste in Hiring and Discharging Employees*

A Discussion of an Important Industrial Problem

By Magnus W. Alexander

It has pleased your President to style as an address what I wish to present to you in an informal way in reference to an investigation into the economic waste of unnecessarily discharging employees. I have not heretofore spoken publicly on the subject and have unsuccessfully tried to dodge it at this time mainly for the reason that in order to give proper background to the statements which I desire to make I ought to present corroborating figures and facts but cannot do so without divulging information given to me confidentially by a number of manufacturing concerns throughout the country. I shall be obliged therefore to use as illustrative figures aggregate statistics of several concerns rather than concrete examples of individual employments.

Every one who is an executive knows how disheartening it is in industrial life to be obliged occasionally to dismiss employees in obedience to business conditions and not at all on account of any fault of such employees. Disregarding the personal and human aspect of the problem and looking at it solely from the cold business standpoint it is at once clear that every unnecessary dismissal of an employee means a definite economic loss to the employer. If through the adoption of different methods than are now in vogue this economic waste can be prevented either in whole or in part it becomes a duty of the employer to himself and to his employees to re-arrange his methods of employment in accordance with improved standards. Many employers have recognized the truth of this statement and have found it profitable to maintain specialized employment departments in charge of competent managers. They know from experience that it does not pay to hire and discharge haphazardly; they realize that it costs money to train an employee even a skilled workman in the special practices that are peculiar to a given concern and that the dismissal of an employee except for good reasons means that the expenditure for his training has gone for naught and that an additional expense must be incurred in the training of a new employee.

Appreciating the situation I have given some time and thought to this subject and will present to-day an outline of my findings. I hope at the same time to make employers recognize more fully than they have in the past the importance of this phase of economic management.

A great deal has been said in the last few years and properly so about reducing the cost of production through so-called scientific management which endeavors to eliminate every unnecessary motion and every unnecessary expenditure. Hand in hand with if not even preceding this effort should go a well-directed endeavor for a closer analysis of the men whom we take into our employ, of the systems under which we train them in our work and of the reasons for and the methods under which we let them go only to have their places filled again by new recruits.

My observations were concerned with large, medium size and small manufacturing concerns throughout the United States all of which form a part of the mechanical industries. During the summer of 1913 while in Europe I made similar investigations in factories in Austria, Germany, France and England. Information and statistics from these European factories would indicate that the problem under discussion is not only a national but an international one; it is so much the more surprising therefore to find that it has received so little serious attention by sagacious business men on this and the other side of the ocean.

The investigation endeavored first to trace the curve of engagements and discharges in the various concerns during the period of one year and then to secure and study the reasons for the discharges in order to find if possible practical remedies for the resulting situation. All data were obtained for the year 1912 which may be considered to have been an industrially normal year.

The investigation covered the employment and discharge of all classes of employees at the various factories except those belonging to the commercial and engineering organization and to the general executive staff. A record of those who had entered the service of the concerns for the first time and of those who had been working in the same place at a previous period was also obtained, for it was assumed that re-employment would usually cause a smaller expense than the employment of entirely new people unfamiliar with the conditions prevailing at a given factory.

*Delivered before the National Machine Tool Builders' Association, New York City.

For the group of factories for which I shall present figures in the aggregate it was found that of all people engaged during the year 1912 about 73 per cent were entirely new employees and correspondingly about 27 per cent were re-engaged employees. As a general proposition this percentage will apply fairly well to any normal employment in the mechanical industries.

The group of factories just alluded to, covering the employment of male and female persons and a great variety of mechanical manufacture requiring labor ranging all the way from the highest skilled to entirely unskilled workmen gave employment to 38 668 employees at the beginning and 46 796 employees at the end of the year 1912. *The increase in the working force as between January 1st and December 31st, amounted therefore to 8 128 people. Yet the records show that during the same period 44 365 people were engaged indicating that 36 237 people had dropped out of the employment during the year for whatsoever reason.* In other words about 5½ times as many people had to be engaged during the year as constituted the permanent increase of the force at the end of that period.

Several reasons might be given in explanation of this condition. It might be stated that the labor market in a given locality was in part responsible for the situation. It might be claimed that in a particular plant a temporary piece of work had to be done, such as the digging of a foundation or the building of a structure for which labor in excess of the normal quota was needed temporarily to be dispensed with again when the special work was finished. Unusual conditions of employment may be pointed out as the result of a highly fluctuating productive situation brought about in turn by a largely varying commercial demand on the factory during the four seasons of the year. Finally sight must not be lost of the fact that some people die, others drop out on account of prolonged sickness and still others leave the employment for reasons that could not have been obviated by the management.

The important fact, however stands out that 44 365 people had to be engaged during the year to retain less than 20 per cent of that number.

Theoretically only as many people ought to have been hired as were needed permanently to increase the force. As business men we know however that theoretical conditions do not surround our commercial enterprises and that we must make certain allowances in order to view the problem in its practical aspect. Accordingly we must admit that

(a) Men die and must be replaced.

(b) Men leave on account of sickness for sufficiently long periods that their places must be filled by others.

(c) Men even though they have been selected for their positions with good judgment leave of their own accord because they do not find it possible to remain in their new positions whether on account of climatic conditions, domestic affairs or other reasons necessitating their removal from the locality.

(d) Finally it must be recognized that no employment department can run on a 100 per cent efficiency basis.

Taking these items into account it must be clear that more than X people will have to be hired during a year in order to increase the working force by X persons. In an attempt to assign values to the four causes just enumerated I have assumed that annually

1 per cent of all employees die,

5 per cent leave on account of prolonged sickness,

10 per cent withdraw for reasons that could not have been foreseen at the time of their engagement, and

75 per cent constitute a readily attainable efficiency of an employment department.

These figures find their support in the following considerations.

After ascertaining the average age of employees in the group of factories under investigation, namely 31¼ years for male and 23 years for female employees, I turned to insurance statistics and found that 8 5 out of every 1 000 male persons of 31¼ years of age and 7 95 out of every 1 000 female persons of an average age of 23, engaged in general factory employment, die annually. The experience of several mutual benefit associations in factories some extending over a period of almost 10 years revealed that annually almost 7 in every 1,000 members were removed by death. These statistics, then fully corroborated my assumption that death removes 1 per cent of factory employees annually.

Insurance statistics also show that about 6 per cent of average factory employees are sick annually for periods of two weeks or more, this percentage drops [illegible] when sickness of three weeks' duration or more is taken into account. Again, the experience of mutual benefit associations fairly well agrees with the data of insurance companies. Knowing, however, the prevailing custom in most factories to carry on sick leave for much longer periods than two weeks those of whose sickness the management has definite knowledge, I have assumed that 5 per cent of all employees will have to be replaced on account of prolonged sickness and consequent withdrawal from the service.

As to the number of people who withdraw during the year for whatsoever other reason, except that of sickness and death no reliable experience seems available. In fact the only information that I could find is that contained in the United States Civil Service report, according to which 8 per cent of all government employees are separated from the service annually for any reason, including that of sickness and discharge. Realizing, however, that governmental employment conditions are different from those in industrial establishments, I have doubled the government estimate by allowing 15 per cent for withdrawal by death, sickness and resignation, or 10 per cent for withdrawal by unavoidable resignations alone.

Finally, I believe that a 75 per cent efficiency of an employment department and even a greater efficiency should readily be attainable in a highly specialized department in charge of one or a few persons.

It follows therefore that while theoretically 8,128 people should have been employed to allow for an increase of the working force by that number, 11 825 persons should have been engaged in addition to cover withdrawals by death, sickness and resignation, and to allow for practical employment results. If we take cognizance furthermore of normally fluctuating productive conditions necessitating at times more and at times less employees, and of unpreventable exigencies of the labor situation, we could make a further allowance of 2 187 persons, representing 5 per cent of the total working force throughout the year.

While theoretically, therefore, only 8,128 persons should have been engaged practically the engagement of 22 140 could readily be defended.

What should be said, however, of the fact that in order to increase the force during the year by 8 128, 44,365 total had to be engaged, of whom 22 225 were therefore engaged above the apparently necessary requirements?

It is obvious that a considerable sum of money must have been wasted in engaging and correspondingly discharging unnecessarily so large a force of men and women. In order to secure a lucid picture of this fact I have tried to assign a dollar-and-cents value to the figures just quoted. No reliable investigation seems to have been made and published in respect to such financial valuation. Industrial managers were therefore, interviewed in an effort to obtain from them if possible a consensus of opinion. They were rather loath to express their views because they had not given heretofore serious thought to the question. Their estimates ranged from $30 00 to $150.00 per employee, few placed the financial valuation of the waste at less than $50.00 per employee and some went even as high as $200 00 per employee. The great difference in these estimates is no doubt due to the diversity of the industries which these managers represented.

One machine tool builder, who is usually very keen in following up matters of this kind, after they have been called to his attention, looked into the subject with some care and stated it as his belief that the engagement of almost 1,000 persons in his plant during one year, while the permanent increase in his force amounted to less than 50, reduced his profits by fully $100,000.00; he therefore estimated the [illegible] waste of the unnecessary engagement of an employee at about $100.00. The head of a large automobile manufacturing company stated with equal positiveness that the engagement of a new employee would involve an expenditure of not less than $100.00. This statement is so [illegible] in [illegible] paid in the automobile industry [illegible] [illegible]

[illegible]

[illegible] new employee has much bearing upon the amount [illegible] that needs to be expended for his training [illegible] important consideration is whether the new employee is working on expensive or low priced machinery or with high or low priced tools, or on expensive [illegible] material; and to a certain extent whether or not he has been employed before in the same shop and [illegible] on the same class of work.

This thought led me to subdivide the employees under investigation into several groups and to study each group as to its requirements for the training of an employee both as to quantity and quality of the instruction. Accordingly, I established the following classes

Class A, comprising highly skilled mechanics who [illegible] have practised their trade for a number of years in order to attain the required high degree of all-round [illegible] and proficiency,

Class B, comprising mechanics of lesser skill and experience, who likely could acquire an average degree of proficiency within a year or two,

Class C, composed of the large number of operatives usually known as piece workers who without any previous skill or experience in the particular work attain efficiency within a few months, depending on the character of the work.

Class D including all unskilled productive as well as [illegible] laborers who can readily be replaced in the course of a few days and

Class E, comprising the clerical force in shop and office.

The employees assigned to each class were again subdivided in the ratio of 73 per cent to 27 per cent to separate those that may be assumed to be entirely new recruits from those who may be considered to have had previous experience in the same factory.

On this basis, the following distribution of the employees was obtained

In Class	Total Engagements			Unnecessary Engagements		
	All	New	Old	All	New	Old
A	4 961	3,549	1,412	2 445	1 785	660
B	6 519	4 759	1 760	3 205	2 394	811
C	15 087	11,014	4 073	7 558	5 517	2 041
D	14,905	10,881	4 094	7 457	5 441	2 016
E	2 973	2 170	803	1 489	1 087	402
All	44 365	32 387	11 978	22 225	16 224	6 001

The next question is What factors mainly contribute to the cost of training a new employee?

This cost may be considered to result from

(a) Clerical work of hiring,

(b) Instruction of new employees by foremen and assistants,

(c) Increased wear and tear and damage of machinery and tools,

(d) Reduced rate of production during early period of employment, and

(e) Increased amount of spoiled work by new employees

The expense of the clerical labor of hiring will be small per individual, somewhere in the neighborhood of 50 cents for each employee.

The instruction expense, on the other hand will vary largely in amount according to the skill and experience of the new employee and the nature of his work It will be lowest for Class D and highest for Class C employees for the latter must be instructed most and watched longest Without now taking the time for a detailed explanation of the conclusions, I feel justified in assigning the following expense values, to wit

Per Employee

Class A	$ 7 50	Class D	$2 00
Class B	15 00	Class E	7 50
Class C	20 00		

The value of the increased wear and tear and the damage of machinery and tools by new employees is difficult to estimate It will be little if anything for Class D and E employees, for whom it may be presumed [illegible] per employee. It may reach thousands of dollars for damage to expensive machinery in the keeping of Class A, B, and C employees for whom an amount [illegible] would be very reasonable

The loss due to reduced production is entirely dependent upon the value of the produced article and the [illegible] and skill required for its production. On the basis of some investigation as to how soon employees in the various classes are able to reach normal productive efficiency in a factory new to them, and with due regard [illegible] average wages, I have assumed the loss [illegible]

Per Employee

Class A	[illegible]	Class D	$ 5 00
Class B	[illegible]	Class E	20 00
Class C	[illegible]		

[illegible] spoiled work, which [illegible] of the raw material and the labor [illegible] for each Class A, B and C employee and practically nothing for Class D and E employees

The respective totals of these items show that the cost of training new employees amounts to the following

Per Employee

Class A	$48 00	Class D	$ 8 50
Class B	58 50	Class E	29 00
Class C	65 50		

Bearing in mind the assumption that about 27 per cent of newly engaged employees had worked before in the same factory the cost of their new training should be considerably reduced even though this reduction would seem justified only if the employee were put back on exactly the same class of work upon which he was previously engaged A conservative estimate would place the expense of breaking in re-hired employees at $10 00 in Class A $20 00 in Class B $35 00 in Class C $5 00 in Class D and $10 00 in Class F for each such employee

Out of these considerations grows the astonishing conclusion that the apparently unnecessary engagement of 22 225 employees within one year in the group of factories under investigation involved an economic loss of $774 139 00

This means that the cost of training a new employee taking all in all amounted to $34 85 or about $35 00 which not only comes within the range of estimates heretofore mentioned but brings the figure practically near the lower limit of the estimates

This important question immediately arises How can this unnecessary loss of about three-quarters of a million dollars be avoided in future if not entirely at least in part?

Five answers present themselves readily

1 An adequate study of current employment statistics and a careful analysis of the reasons for the discharge of employees will furnish a fact basis of great value

2 High-grade men must be placed in charge of the hiring departments of concerns

3 The exercise of proper methods for the taking care of new employees is an exceedingly important problem

4 Effective systems of apprenticeship and specialized training courses must be maintained and

5 Commercial requirements should be so regulated as to secure a fairly uniform productive situation through out the year

It should be unnecessary to point out that the reasons for the voluntary or involuntary leaving of an employee as given by the foremen on the discharge cards cannot be fully relied upon and that special effort should be made to get at the real reason for an employee's discharge so as to secure a correct basis on which to build remedial action

In the light of the above statements and figures it should also be unnecessary to defend the necessity for the highest grade of judgment in the hiring and discharging of employees The employment clerk of to-day will have to be replaced by the employment superintendent or manager of to-morrow not merely by changing the title of the man but by changing the type and character of the man even though this will mean a higher salary Second in importance to the manager of the plant should be the assistant who is entrusted with the duty of bringing into the plant the men and women that are needed from time to time and of keeping them there contented and efficient What methods to employ to take care of employees from the very moment when they start in their new work is a far more important question and presents a far more difficult problem than that of the proper selection of new employees from among the applicants for the job The very best thought on the psychological side of industrial management will have to be applied to this particular phase

It has been recognized for some years even though not perhaps as fully as should be that it is the duty of industrial managers so to take hold of the youth of the land and properly train the boys and girls who wish to or by circumstances may be obliged to choose a vocational occupation for their livelihood, that they may become intelligent skillful and contented workers and leaders in our constantly growing industrial army Although to a certain extent all managers take an interest in this problem of providing an adequate supply of properly trained workers, many have not yet discovered that it will be essentially worth while to set aside the required time from their busy life and to devote appropriate effort and financial support to this issue

As for the last suggested remedy to bring about a more evenly arranged production throughout the year, I can only express the belief that much good to all concerned can be accomplished in this respect, and I am encouraged in this feeling by the growing examples of standardization of product which brings with them ability to manufacture for stock as well as for immediate delivery, thereby permitting the maintenance of a fairly even production throughout the year

Along the five lines of remedy herein suggested lies, to my mind the solution of a problem which looms large before our eyes and will loom larger as competition will grow keener The Man problem as contrasted with the Material and Machine problems will and must in future engage more fully and more keenly our best attention

It is somewhat reassuring at the present time although it may not remain so for long to know that the conditions of employment herewith presented do not seem to be any better in European industrial countries Merely in support of this statement the following illustrations drawn from factory experience in Germany and England may be of interest

Factory	Employees at Beginning of Year	Employees at End of Year	Total Increase During the Year	No Persons Hired
1	13 556	16 450	2 894	9 530
2	10 998	11 914	916	17 059
3	9 165	12 032	2 867	10 962
4	3 158	3 149	Minus 9	2 148
5	365	470	105	637

In presenting to you the results of my investigation into the waste of hiring and discharging employees I have made no effort to paint a black picture but have merely presented the varied colors of the industrial spectrum I have pictured what seems to be an average condition throughout the country Time has not permitted to place before you a detailed analysis of the contributing causes and remedial actions for the problem under discussion however a word to the wise is sufficient

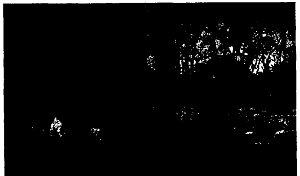
I now close with an earnest plea that you give the problem careful consideration and indulge in similar investigations in your own factories to assure yourself of the state of your affairs and where necessary to correct unsatisfactory conditions It will also give you a more concrete knowledge of the subject so that a future discussion of it may be conducted with a more assured hopefulness of finding and applying the right remedy or remedies for an unsatisfactory situation Through a correct solution of the problem we shall not only contribute materially to the welfare and prosperity of the industries but also to the contentment and well being of the thousands and thousands of employees who cannot be benefited in any degree by short-time and haphazard employment

In view of certain legislative and administrative tendencies now affecting American industries it is important also to reflect that constant fluctuation in the working force of an establishment must materially increase the difficulty of maintaining among the employees loyalty to the management *esprit de corps* and general contentment Just as little as we shall be able to take quicksand and knead it in our hands into a solid lump so also will we find it impossible to take hold of an ever-changing mass of employees and transform it into a homogeneous intelligent contented body furthermore this condition will nullify to a large degree the beneficial effect of many well intentioned efforts of the management such as sickness and accident insurance plans pension systems and other phases of industrial betterment work

And last but not least *the problem of employment offers an opportunity for constructive work in which employers and employees can readily be brought together for mutual benefit* for no right-thinking man whatever his position can justly object to any well-directed plan which will give employees continuous work through out the year and will enable employers to maintain steady production

Properties of Selenium

An extremely interesting report of an investigation of the crystal forms of metallic selenium by Mr F C Brown recently appeared in the *Physical Review* In this research a large number of new crystals of metallic selenium were formed, some of very large size. All of these forms, except one, are very transparent selectively to light, a large amount of light penetrating to a greater depth than 0 2 millimeter All the crystal forms increase in conductivity when illuminated and with but one exception they have been observed to be doubly refracting. The action of light is in the selenium itself and not at the contacts. Mechanical pressure produces a genuine change in the selenium, which may alter the conductivity more than a thousand times. The absolute change of conductivity in one crystal by constant illumination was proportional to the conductivity in the dark, when that conductivity was altered by pressures between 1 atmosphere and 180 atmospheres. The temperature at which the crystals sublimate in mass influences the character of the wave-length sensibility curves. The production of individual crystals of metallic selenium of large size opens up a wide field of investigation which promises to be free from some of the possible complexities in selenium cells.



The common method of navigation of small streams by the native Panamanians is by means of the *cayuco* or dugout, which varies in length from eight to thirty-five feet, and is cut from a single tree. These boats are used by the natives for bringing fruit and produce to market, and it is a common sight to see them loaded with sugar cane cut in sections eight or ten feet in length.

The low entrance to limestone cave on the Chilibrillo River opens into a series of long corridors and chambers more or less intercommunicating.

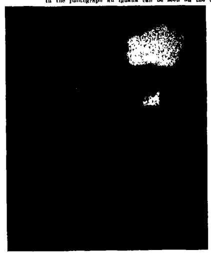
Waterfront of Panama City, where the boats come in to market, in the early morning, loaded with fruit and vegetables from the neighboring islands.

Flashlight of small cluster of bats before alarmed.

Clusters are ordinarily formed of a great number of individuals, probably several hundred in some instances. The variety shown is one of the largest of South American bats, one specimen secured having a wing expanse of twenty-six inches. The bats are strong and muscular and always ready to bite. The masses of bats bear close resemblance in form to the stalactites with which the walls and domed ceilings are covered.

Newly flooded forest on the Rio Trinidad.

Rivers in the Gatun region have risen, as this photograph indicates. The lake of the region, previously a negligible one, has now an extent of one hundred and sixty-four square miles and a depth in places of seventy to eighty feet. In the photograph an iguana can be seen on the upright stump and a white egret on the log at the center.



In a bat cave.

Showing method of photographing bats by flashlight. As the flashlight powder used is exceedingly explosive the expression of apprehension on the face of the operator is not to be wondered at.

The black howler, the largest of the Panamanian monkeys, is looked upon by the natives as a weather prophet, its loud, long, and reverberating howl being most frequently heard just preceding a heavy rain.

Flashlight photograph of one of several varieties of opossums encountered in the Canal Zone.

The particular opossum shown is the commonest species and by reason of its abundance and its omnivorous appetite, it proved a serious obstacle to flashlight photography. Probably seventy-five per cent of the flashes fired were sprung by opossums who found and fired the camera shortly after dusk before better game was moving.

Flashlight photograph of bats.

Although these caves were inhabited by several different species of bats, it was found that, for some reason not clearly apparent, each species isolated itself in a particular grotto. Not only this, but the different sexes of each species was found similarly separated and isolated.

Flashlight picture of paca (Agouti paca virgata), one of the largest of the existing rodents, the closely related carybara alone exceeding it in size.

The paca is an animal of nocturnal habits and, therefore, can be photographed only by means of flashlight apparatus set at night. Note in the animal's mouth the mango which was used as bait. This is one of the game animals of the natives who call it *conejo pintado* or spotted "rabbit."

It was because of the flooding of the Gatun Lake basin by the huge dam at the Gatun locks, thus causing abrupt changes in the faunal conditions, that an expedition under the patronage of Mr George Shiras, 3rd, was undertaken. The houseboat formed the base camp from which trips were made by launch or small boat, sometimes along rivers which heretofore have been inaccessible owing to shallow water. The houseboat had sides of cheese cloth and copper screen to keep out mosquitoes.

Scene on the Rio Chilibrillo up which trips were made to visit the bat caves.

As palms never grow in water, something of the extent of the flooding of this region can be judged.

Lake end of Gatun locks looking out over Gatun Lake.

Three different stages in filling the locks are shown, the lock at the left being empty, the one in the lower right-hand corner half full and the one in the upper right hand corner full. Emergency dams are seen in the background. Four locomotives similar to the one shown are to be used for each ship, two being in front and two in the rear.

Views in the Panama Canal Zone Secured by the Expedition Investigating the New Faunal Conditions Since the Gatum Lake Was Created

New Faunal Conditions in the Canal Zone

Notes of an Expedition to Investigate the Results of the Physical Changes in this Region

By H. E. Anthony

During the months of February and March of last year it was the good fortune of the author to accompany, as an American Museum representative, Mr. George Shiras, 3rd, on a trip to the Canal Zone. Mr. Shiras desired to obtain photographs by flashlight of the animal life of that region, a method of which he is one of the foremost exponents to-day and which has yielded him some remarkable results in temperate regions. It was through his generosity that the Museum was able to send a collector to Panama with him.

It was expected that faunal conditions in the Canal Zone would be undergoing abrupt changes because of the damming of Gatún Lake and the consequent extensive high water. From a basin with no lake worthy the name, with standing water confined largely to marshy areas except during the height of the rainy season, the Gatún region has been transformed by the huge dam at the locks into a lake of one hundred and sixty-four square miles in extent and a depth of seventy to eighty feet in many places. This flooding of ground formerly high and dry, it was anticipated, would drive many animals to seek new homes or might even threaten some of the more restricted, lowland-living animals with extermination. Incidentally many of the islands and ridge crests left above water might have a concentrated fauna driven there from the adjacent flooded localities. Other phases of the question dealing with the newly created lake were the wiping out of the lowland forests by submergence, the rise of new aquatic flora, such as the water hyacinth, and the probable inhabitation of the lake by water birds. Such were some of the items in the purpose of the expedition and we were equipped to take advantage of these new conditions if the foregoing assumptions proved correct.

As Gatún Lake was the center of investigation, it was planned to work from a house boat as a base camp, with a launch and small boats for side trips. Accordingly a boathouse was made over by a few alterations, but only after considerable time had been spent in trying to secure something available for the purpose. The house boat was so low in the water that she could be towed only in a calm sea, a condition of the lake only rarely met with, and at best the launch could make but slow time pulling her. Late afternoon of March 6th saw us leaving Gatún with the house boat and by 3 o'clock the next morning we were tied up at the head of a waterway or *trocha* that branched off from the Rio Trinidad. This was our main camp and we hoped to be able to work the undisturbed jungle from here. Unfortunately, a plantation nearby, a young fruit district only recently made accessible by high water, chose this time to burn over some clearings, and we found that the smoke materially interfered with our success. Cameras with flashlights and bait were set out in promising spots, lines of traps for mammals were run daily, while the jungle was hunted in hopes of shooting specimens.

It was at this spot that we made the acquaintance of the largest of the Panamanian monkeys, the "black howlers." Frequently their queer booming, roaring howl echoed through the jungle, a call that carries for long distances. They howl oftenest just before or during a rainstorm and the natives thus look upon them as weather prophets. Upon one occasion I stood almost under some trees through which a troop was passing, while the first big preliminary drops of a sudden shower pattered upon the leaves about me. The volume of sound that issued from the black shaggy throats was so great and so suggestive of a large animal, a lion for example, that I found it hard to reconcile myself to the actual facts. I felt a pang of regret at silencing one of the "howlers," but as a specimen was needed I shot one of the foremost and heard him crash through the limbs to the ground. Pangs of a more effective sort were experienced when my native boy and I attempted to retrieve the monkey, for he had fallen underneath a bees' nest the size of a bushel basket and we found the nest too late to avoid it.

Other interesting mammals encountered here were the pretty squirrel-like marmoset, the short-haired anteater and several species of opossum, while we were continually wondering at the variety of the bird life and the diversity of the bird songs and callnotes. The noisy parrots that shouted in the morning until the jungle rang with their tumult, the grotesque toucans which at times vied with the parrots, the calling of the parrakeets, and the peculiar chorus-like calls of the chachalaca, or "wild turkey," produced an impression that must ever be associated with jungle memories. At night mysterious noises were heard from unknown sources, and one weird laughing call in particular caused conjecture to run rife, there being as many opinions as there were listeners.

Besides the work done on the Rio Trinidad, several long trips were made by launch far up the river as the launch could ascend and two others up the Rio Chilibrillo to some limestone caves for bats. On these trips it was found that the rising waters had ascended far up the river valleys, which in this part of the region have very little fall, making them navigable to launches where formerly it would have been impossible to take a cayuca or native dugout. Some of these flooded rivers—rivers by courtesy, for in the States these streams would be called creeks—with their banks densely lined by jungle vegetation which met overhead and dropped long vines and streamers into the waters, were very beautiful.

Everywhere we found the forest inundated. In regions early flooded, where the trees were submerged for the greater part of their height, all the trees were dead and leafless with an occasional great clump of orchids, the only green left. Many square miles of the surface of Gatún Lake are thickly studded with dead tree-tops of what was at one time splendid tropical forest. In regions of later high water many of the trees were still green and blossoming; especially was this so along the shores where but the lower part of the tree trunks were under water. It is not improbable that some of the more resistant trees may live to a ripe old age with their roots some feet below the surface of Gatún Lake, for some species were found flourishing among their long since dead companions. No new aquatic growth, arisen to take advantage of the altered conditions, was noted, but the conditions had probably not been in operation long enough to bring about such a growth. The dead trees are constantly falling and the far-reaching crash of their descent is one of the common sounds of the lake.

Gatún Lake will undoubtedly produce new economic conditions among the natives of the adjacent district. These natives formerly had no other waterways but the few rivers that traversed the interior basin, and were available for navigation only to a limited number of villages. Such rivers were the Chagres, Trinidad, and Gatún. Now the far-extending lake shores provide such an accessible waterway that the natives are learning to navigate on lake waters, and every morning their *cayucas* may be seen lined up at the native market along the lock-front at Gatún. Being primarily river boatmen, however, they are yet somewhat distrustful of the lake winds and do most of their traveling at night when the winds die down. During the dry season, from January to April, the winds blow across the lake toward a northern quarter of the compass, and just the reverse holds true for the rest of the year. This wind at times becomes strong enough to threaten small boats seriously, and at practically all times of the day would be a strong check on the progress of the native dugout that was facing it. We found it necessary to move the house boat always at night and in the early morning hours because of this wind, and this proved a serious obstacle to working many localities, because it was out of the question to run at night without a moon, and when we most wished to move we had a late rising moon. After driving the launch full-tilt over a floating tree and into partially submerged bush and tree tops, trying to steer by lantern light, we confined our future movements to moonlit hours.

Whenever one left the waters of Gatún Lake the dense, unaltered jungle was at once encountered and no matter how much its beauty was to be admired from the boat, its impenetrability was no less to be deplored. It was useless to attempt to leave the trail without recourse to the machete, the long brush knife of Latin America, and many were the varieties of briars and thorns to be avoided. Once into the thick growth of the jungle, the hunter found it necessary to stand [illegible] in one spot in order to look into all the arboreal [illegible] and crannies, so many were the possibilities, [illegible] the great orchid-covered limbs and [illegible] and so loath to leave the [illegible] orchids and epiphytes [illegible] and became so heavy a burden at times [illegible] down the limb or even the entire tree [illegible] them, and not infrequently I witnessed the [illegible] some tree overburdened in this manner [illegible] warned by a premonitory cracking, I [illegible] move with considerable speed to escape [illegible].

Mosquitoes, the former bane of early Canal [illegible] were found but sparingly. Even outside the [illegible] government patrol we were bothered but little by them, although we were told that later, during the rainy season, they were much worse. A few spots were encountered where mosquitoes were bothersome, [illegible] arguing a local distribution. The ticks and red bugs, however, made up in diligence for any slights we might feel we had suffered from not being met by mosquitoes. The jungle everywhere seemed to harbor these pests and they did all they could to make life miserable for us. Ants also were found in abundance and it was fortunate indeed that our camp was a floating one and thus cut off from inroads of these nuisances. One species of ant in particular will be long remembered by two members of the party, for it stung with a venomous vigor never equalled by any bee and made the victim imagine he had been struck by a snake at least.

Concentration of animal life had taken place at the rising of Gatún Lake, and most of the islands formed had many inhabitants at first. The Gatún Hunt Club, however, soon reduced the population of these islands by hunting them with hounds, and as the quarry in most instances could not leave the island, the result was a clean sweep of all the larger species. We were too late, consequently, to find abundant game on any of the islands near Gatún. I accompanied this hunt club on one occasion, securing two peccaries.

The most efficient method of hunting the Panamanian jungle was by means of a headlight at night. The rays of the light, worn on the hunter's head, are reflected by the eyes of the animal, which shine like two orbs of fire—red, green, or bluish, depending on the animal "shone." The hunted animal will see nothing but the approaching light and falls an easy victim to the rifle or shotgun. On account of the danger to domestic stock and to people by promiscuous shooting at night, this method has been prohibited on the Zone, but beyond Zone limits it is to-day the favorite mode.

The trip resulted in a good series of flashlight photographs of opossums and some of the smaller mammals. The apparatus for "flashing" the animals was set out by some runway or water-course where animals were apt to pass, and consisted of a mechanism to fire a magnesium flash and at the same time trip the shutter of the camera, which was fastened in a manner to command the trail. A thread attached to a bait and stretched out before the camera fired the flash when the animal pulled it.

Series of the rodents and the smaller mammals were secured for the Museum collections and for the most part are of species not hitherto represented. The time was too limited to secure many of the larger mammals which are found in the Zone.

* The expedition worked under authority from the Canal Commission. It is of note that Colonel Goethals, as the first civil governor of the Canal Zone, continues adherence to the policy he maintained during the engineering work in the region, namely, that the Isthmus shall be a game preserve. Exception to the observance of the laws against shooting game outside a short open season will be made only in favor of such occasional zoological expeditions. Reprinted by permission from the *American Museum Journal*. Illustrations by courtesy of Mr. George Shiras, 3rd, who organized the expedition and made the flashlight photographs; and also of the author, who photographed the general scenes.

Electric Power for Agriculture

The idea of applying electric power to agricultural operations is attracting attention, especially in view of the great hydro-electric plants that are being developed in districts remote from present manufacturing activities, where the power must be transmitted great distances. If some of this power could be utilized locally it would be a good thing for both the producer of electricity and the user, as it would [illegible] thing steadily lead to increase [illegible] this in turn would cause the power to be sold at a lower rate, as more power would be [illegible] increasing the overhead expenses. One [illegible] cation of electricity in some districts [illegible] running irrigating pumps, and this could [illegible] nomically if enough power was taken to pay for the installation of the lines. [illegible]

Protection Against Torpedoes*

A Discussion of the New Conditions Created by Mines and Submarines

Although the cause of the sinking of the "Formidable" in the Channel on New Year's Day is not known to the public with any certainty, it is generally assumed that either a torpedo or a mine was responsible. If a torpedo was really the cause, then the highest praise is due to the German submarine which fired it. The weather was extremely rough at the time and the difficulties to be encountered were enormous; so great, indeed, that we are almost prepared to regard them as insuperable. If, on the other hand, we accept the alternative, we are faced with the problem how a German mine got so far west. We say a "German mine," because there is some reason for believing that the Germans are not careful to ensure that their fixed mines go automatically out of action, as ours do, when they break adrift from their moorings, and they alone use the barbarous free floating un-timed mine. Probably the Admiralty is in a position to say which of these two causes, both of which have elements of improbability, was really responsible, and we are not likely to know for a long time to come. In the meanwhile the problem of the resistance of ships to submarine attack has been raised by this latest loss.

The subject is one that has attracted a great deal of attention in recent years; but, on account of the new policy pursued by the Admiralties of most countries and of our own particularly, very little is known outside a limited circle, as to what steps have been taken to guard against this ever-increasing danger. As we shall show presently, it is probable that no country fully appreciated the submarine menace when the war began. Until a few years ago there was never any question of armoring ships' bottoms. It was thought that a moving ship could generally maneuver out of the way of a torpedo when it was conscious of the direction from which it came, as, for example, in the case of an attack from a destroyer. Protection then was only needed when the vessel was at rest, and for this purpose the torpedo net was given to all ships of any size. The net, however, is no longer an infallible defence against modern torpedoes, and since the development of the submarine, with its invisible attack, the stationary or slow moving ship is at a great disadvantage. A new method of defence is needed. The problem is one of extreme difficulty. There are only two lines on which a solution is to be sought if complete immunity is to be found. Either the bottom plating of the vessel must be made so powerful that the explosion of a torpedo against it can cause little damage, or means must be discovered for keeping the torpedo at a distance. In harbor it is not very difficult to ensure the latter. Obstacles may be placed to guard the entrance and, as a secondary precaution, the nets may be lowered on the ships themselves. In the open sea such protection is impossible, and the only course is to depend upon speed, maneuvering qualities, and gun fire. By these means the submarine may be driven off or avoided, and it is also conceivable that in certain states of the sea, when its approach is made visible by its wake, the torpedo might be sunk or exploded by gun fire with suitable projectiles. Generally speaking, however, recourse to such means is out of the question, and safety lies only in the discovery and destruction or avoidance of the attacking vessel. Where the latter is a submarine and the water is broken the difficulty is great, and the best defence remains irregular speed on an irregular course. We are thus left with the fact that no mechanical means have yet been discovered to prevent a well-aimed torpedo striking its mark with, in the case of older ships at least, fatal effect. The only hope, then, lies in so constructing the bottoms of ships that the submarine explosion shall do no or only localized injury. It is on this line that architects are working.

Whether or not the bottoms of our latest ships are armored we cannot say; but even if they are not, which is probably the case, a form of subdivision similar to that employed in recent French ships—the "Bretagne" class for example—is used. In general terms this consists in forming a long internal caisson or cofferdam inside the vessel at the vulnerable under-water parts. It forms in fact a kind of double skinning, only that the space between the outer and inner skin is greater than in passenger vessels and the inner skin is made thick and of a particularly tough kind of steel. Occasionally a flexible diaphragm is placed midway between the two skins, and helps to protect the inner one against injury. The force of the explosion of a mine or torpedo expends itself in destroying the outer skin and is unable to damage seriously the inner. The ship is, of course, badly injured, but not sunk. We know that this plan has been adopted in British vessels, for Mr. T. G. Owens has stated that "in most of the later ships there are submerged longitudinal protective bulkheads to ward against the effect of submarine explosions, either from torpedoes or mines" (Inst. N.A.), and we have good grounds for hoping that any of the latest battleships and battle-cruisers would not suffer the fate of the old vessels that have been sent to the bottom by the invisible attacks of the enemy; but we may ask how long after such an explosion would the damaged vessels again be available for service. "Sub-division," said Sir John Biles at Newcastle last July, "naturally suggests itself as one means of minimising the effect of this damage; but, when all that is possible in this direction has been done, there seems to be no great certainty that a battleship will still be a formidable fighting machine after having received the successful contact explosion of a 21-inch torpedo." He then asked, "Can we do anything in addition to sub-division to preserve the ship for effective fighting purposes?" and replied, "The effective advent of the submarine seems to justify a serious consideration of the question of applying armor to the bottoms of ships." Sir John then showed that if the bottom was to be armored with 4-inch plates, which he suggested would be needed, a reduction in speed of two knots or a diminution of above-water armor would be necessary.

Speaking on this paper, Sir Philip Watts made one or two remarks that give us some insight into the course adopted by the Admiralty. He said: "Defence can be provided by fitting deep inner bottom spaces backed with tough protective plating, by which the loss of buoyancy resulting from a hit may be considerably restricted," and "Up to the present time the submarine menace has not been considered of sufficient importance to justify the adoption of armor for protecting the bottom; although discussed from time to time it has never been fitted." Sir Philip Watts and many others may now see reason to alter their views, but it must be remembered that with a single possible exception, about which little or nothing is known save from American sources, no modern big British ship has suffered from mines or torpedoes. Only elderly ships have been sunk, ships that were built when submarines were little considered. On the other hand, it appears that the "Viribus Unitis" was torpedoed recently by the French, and it is reported that a modern French ship of the "Courbet" type (1910) has also been struck, but in neither case has the vessel sunk. There is a rumor also that the "Goeben" has just been torpedoed without sinking. The reason in these three instances may be that in not one did the torpedo reach a fatal spot, but equally it may be that the new form of construction does, at least, save the life of the ship.

It will be gathered from this brief review of the position that while armored bottoms have been discussed, they have not been adopted, but that practically all recent ships are provided with under-water chambers or caissons, on which the explosion of mines or torpedoes can expend themselves, and are in other ways subdivided. The only other protection against submarine attack is the mobility of the vessel herself and the use of nets. Sub-division does not protect a vessel from injury of such a nature that she would have to spend many weeks in dock after a successful attack, and hence it cannot be regarded as final. We are thus driven to the conclusion either that armoring of bottoms must become a general practice or that some entirely new means of repelling or nullifying attack must be found. Here is a problem upon which our readers might exercise their ingenuity. It is, we admit, not very promising, but we suggest as a course which does hold out some hope of success that in the first place means for discovering the position of an unseen submarine might be sought. To know the position of your enemy is to win half the battle, and if we could discover some device which would lend sub-marine eyes to the battleship as the aeroplane has lent super-terranean sight to the general staff, we should be on a long way to avoiding such calamities as have occurred. It is well known that all submarines are noisy and that in a submerged condition they are driven by powerful electrical machinery. We suggest that two lines of research are opened by these facts. A modification of the submarine bell apparatus now fitted to many merchant ships might be used to discover the direction in which a submarine lay, or some delicate device which would discover its position by magnetic means might be invented. The matter, of course, bristles with difficulties, which are increased by the fact that the information on which invention must be based cannot be obtained; yet the more minds are directed to the problem the nearer shall we be to a solution.

On the Temperature of the Mercury Arc*

By J. C. McLennan, University of Toronto

In the course of some experiments recently carried out by the writer on the fluorescence of iodine vapor under stimulation by the light from the mercury arc, it became necessary to know the temperature to which the iodine vapor was submitted during the exposures. As there appeared to be no information available on the temperatures obtainable from such types of mercury lamps as those used in the fluorescence experiments mentioned, a few sets of observations were made and an account of these is given in the following note.

[illegible] who had studied the temperatures in electrical discharges in hydrogen, nitrogen, and atmospheric air at low pressures in Geissler tubes provided with Wehnelt cathodes, has shown that with currents of about an ampere passing in the tubes temperatures beyond 1,000 deg. Cent. have been observed with thermocouples [illegible] exposed to the discharge.

[illegible] temperatures [illegible] also found to characterize the discharge in the mercury arc when a thermo-couple was exposed directly to the luminous vapor.

To bring out this point measurements were made on the discharge in a tube that had a platinum-iridium thermo-couple sealed into it with one junction situated at the axis of the tube. The terminals were joined—one to a standard Siemens and Halske potentiometer, and the other cooled to 0 deg. Cent. by melting ice—and this gave the electromotive forces of the junction when discharges of different intensities were sent through the tube.

In making the observations the tube was joined to the 110-volt direct current supply circuit with a variable resistance in series which enabled one at will to modify the strength of the current in the arc.

Before sealing the wires into the tube the thermocouple was calibrated by exposing the junction to a series of temperatures given by (1) melting ice, (2) water and naphthalene boiling at atmospheric pressure and (3) zinc, coin silver, and potassium sulphate at their respective melting points.

In making observations the fall of potential between the two terminals of the tube was measured simultaneously with the strength of the current passing through it. At the same time the corresponding electromotive forces were read off from the compensation apparatus.

A temperature of 1,400 deg. Cent. was reached when a current of 10.6 amperes was passing through the tube and it was deduced by supposing that the calibration curve was rectilinear beyond 1,070 deg. Cent., the highest point of calibration. Platinum, platinum-iridium thermo-couples are not generally used in measuring temperatures higher than 1,100 deg. Cent., or at most 1,200 deg. Cent., but in the present case it was found that the couple still remained intact when an electromotive force of 196×10^{-4} volts was reached and this was taken from the curve as representing approximately 1,400 deg. Cent.

It is quite clear that with a platinum platinum-rhodium thermo-couple still higher temperatures might have been recorded, but after the maximum current of 10.6 amperes had been running for a short time the tube cracked and the investigation was not carried further.

The investigation shows that with a moderate consumption of energy the luminous vapor in the mercury arc may attain and easily exceed a temperature of 1,400 deg. Cent.

The investigation suggests, too, that in all probability the temperatures indicated by a thermo-couple when exposed directly to the discharge are still very much below that corresponding to the mean molecular kinetic energy of the luminous vapor. The most satisfactory way, though a difficult one, to ascertain the temperature, would be to investigate the form and variation in width of a selected spectral line when the consumption of energy in the arc is varied.

Edward Weston's Inventions

Revolutionizing Discoveries that Resulted from Exact Observation and Original Chemical Theories

By Dr L H Baekeland

The pioneer work of Dr Edward Weston is not easy to describe in a few words His restless inventive activity has been spread over so many subjects has intertwined so many interlocking problems that in order to understand its full value it would be necessary to enter into the intimate study of the various obstacles which opposed themselves to the development of several leading industries which he helped to create the electrodeposition of metals the electrolytic refining of copper the construction of electric generators and motors the development of electric illumination by arc- and by incandescent-light and the manufacture of electrical measuring instruments An impressive list of subjects but in every one of these branches of industry Weston was a leader and it was only after he had shown the way in an unmistakable manner that the art was able to make further progress and develop to its present day magnitude

But why was Weston able to overcome difficulties which seemed almost unsurmountable to his predecessors and co-workers in the art?

The answer is simple He introduced in most of his physical problems a chemical point of view—a chemical point of view of his own a point of view which was not satisfied with general statements but which went to the bottom of things He did not get his chemistry wholesale as it is dispensed in some of our hot-bed method educational institutions He had to get at his facts piecemeal one by one adjust them ponder over them—collect his facts with much effort and discrimination he did not acquire his knowledge merely to pass examinations but to use it for accumulating further knowledge

It seems rather fortunate for him that one of the first employments he got in New York was with a chemical concern which made photographic chemicals This was the time of the wet-plate when photographers made their own collodion their own silver bath their own paper Whoever went through those delicate operations knew the difficulties the uncertainties which were caused by small variations in the composition of chemicals or in the way of using them Photochemistry is excellent experience for any young chemist who is disposed to generalize too much all chemical reactions by mere chemical equations Whoever has to deal with those delicate chemical phenomena which occur in the photographic image knows that many unforeseen facts can not easily be accounted for by our self satisfying but often superficial generalizations of the text-books

Weston's tendency to observe small details in chemical or physical phenomena led him to improve the art of nickel plating and electrolytic deposition of metals to a point where it entered a new era When he undertook the study of the difficulties in this art he took nothing for granted but by close observation he succeeded in devising methods not only of improving the physical texture of the deposit but for increasing enormously the speed and regularity with which the operations could be carried out all these improvements are now embodied in the art of electro typing nickel gold and silver plating

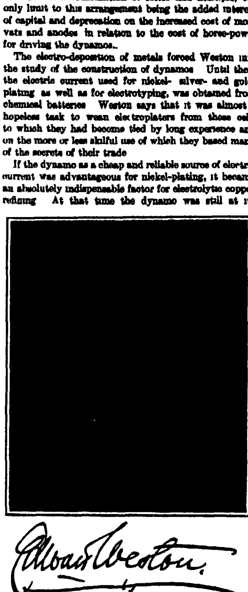
At this time attempts had already been made for the commercial refining of copper by means of the electric current But this subject was then in its first clumsy period far removed from the importance it has attained now among modern American industries Here again Weston brought order and method where chaos reigned His careful laboratory observations harnessed by his keen reasoning intellect established the true principles on which economic industrial electrolytic copper refining could be carried out Prof James Douglas (Commencement address Colorado School of Mines *Metallurgical and Chemical Engineering* Vol XI No 7 July 1913 page 377) referred to this fact in a recent address

I suppose I may claim the merit of making in this country the first electrolytic copper by the ton but the merit is really due him (Weston) who in this and innumerable other instances has concealed his interested work for his favorite science and pursuits under a thick veil of modesty and generosity

The whole problem of electrolytic refining when Weston took it up was hampered by many wrong conceptions One of them was that a given horse-power could only deposit a maximum weight of copper regardless of cathode- or anode-surface This fallacious opinion was considered almost an axiom until Weston showed clearly the way of increasing the amount of copper deposited per electrical horse-power, by increasing the number and size of vats and their electrodes, connecting his vats in a combination of series and multiple, the only limit to this arrangement being the added interest of capital and depreciation on the increased cost of more vats and anodes in relation to the cost of horse-power for driving the dynamos.

The electro-deposition of metals forced Weston into the study of the construction of dynamos Until then the electric current used for nickel- silver- and gold-plating as well as for electrotyping, was obtained from chemical batteries Weston says that it was almost a hopeless task to wean electroplaters from these cells to which they had become tied by long experience and on the more or less skilful use of which they based many of the secrets of their trade

If the dynamo as a cheap and reliable source of electric current was advantageous for nickel-plating, it became an absolutely indispensable factor for electrolytic copper refining At that time the dynamo was still at its



very beginning—some sort of an electrical curiosity It had been invented many years before by a Norwegian Soren Hjorth who filed his first British patent as far back as 1855 Similar machines had been built both in Europe and America, but little or no improvement was made until Weston in his own thorough way undertook the careful study of the various factors relating to dynamo efficiency

In 1876 Weston filed his first United States patent on rational dynamo construction which was soon followed by many others and before long he had inaugurated such profound ameliorations in the design of dynamos that he increased their efficiency in the most astonishing manner Heretofore the dynamos which had been constructed showed an efficiency not reaching over 15 to 40 per cent gross electrical efficiency but the new dynamos constructed after Weston's principles increased this to the unexpected efficiency of 95 per cent and a commercial efficiency of 85 to 90 per cent He thus marked an epoch in physical science by constructing the first industrial machine which was able to change one form of energy motion into another electricity with a hitherto unparalleled small loss As the improvements in dynamos depend almost exclusively on physical considerations, and have little relation with the field of chemistry I shall dispense with going further into this matter But I should be permitted to point out that the first practical application of electrical power transmission for factory purposes in this country, was first utilized in Weston's factory, the success of this installation induced the Clark Thread Works also located in Newark, N J, to adopt this method of power transmission for some special work, a method which now has become so universal For this purpose, Weston had to invent new devices for starting, and for controlling, as well as for preventing injuries to motors by overload.

In Weston's factory also the electric arc was used for the first time in the United States for general illumination

In fact from 1875 to 1886, Weston was very energetically engaged with the development of both systems of arc- and incandescent-illumination by electricity. We see him start the manufacture of arc-light-carbons according to methods invented by him, and thus he became the founder of another new industry in America. He continued this branch of manufacture until 1884, at which epoch this part of the business was transferred to another company which has made a specialty of this class of products and has developed it into a very important industry Here again Weston introduced chemical methods and chemical points of view Among the many objections which the public had against the electrical arc was the bluish color of its light Women especially complained that the blue-violet light did not bring out their complexion to the best advantage Weston first tried to use shorter arcs which gave a whiter light but this was only a partial remedy He soon found a more radical and more complete cure by the introduction of vapors of metals or metallic salts or oxide in the arc itself so as to modify at will the color of the light and thus he became the inventor of the so-called flaming arc. It is noteworthy that it took about 20 years before electricians and illuminating engineers became so convinced of the advantages of the flaming arc, that it had to be 're-invented' during these late years, and now it is considered the most efficient system of arc-illumination

In relation to this invention it is interesting to quote the following extract of the specifications from his United States Patent No 210 380 filed November 4th, 1878

This rod or stick may be made of various materials—as for example of so-called lime glass' or of compounds of infusible earths and metallic salts, silicates double silicates mixtures of the silicates with other salts of metals fluorides double fluorides mixtures of the double fluorides fusible oxides or combinations of the fusible oxides with the silicates—the requirements, so far as the material is concerned being that it shall be capable of volatilization when placed on the outer side of the electrode to which it is attached and that its vapor shall be of greater conductivity than the vapor or particles of carbon disengaged from the carbon electrodes The foreign material added to the carbon may be incorporated into the electrode by being mixed with the carbon of which the electrode is composed or it may be introduced into a tubular carbon but I have found it best to place it in a groove formed longitudinally in the side of the electrode as shown

In his endeavor to make the electric incandescent lamp an economic possibility we see him introduce over and over again chemical methods and chemical considerations He first tried to utilize platinum and iridium and their alloys which he fused in a specially constructed electric furnace, devised by him antedating the furnace described by Siemens This is probably the first electrical furnace, if you will except the furnace which Hare used in his laboratory in Philadelphia

But these platinum metals showed serious defects aside from their high cost and by that time Weston had become so familiar with the properties of good carbon that like other inventors, he became convinced that the ultimate success lay in that direction

And now we see him join in that race of rivalry among inventors who all engaged their efforts in search of the real practical incandescent lamp Among this group of men the names of Edison here in the United States and that of Swan in England, have been best known. To go into the details of this struggle for improvement is entirely outside of the scope of this short review

Edison succeeded in making incandescent lamp filaments by carbonizing selected strips of bamboo. But even a carbon made of this unusually compact and uniform material was far from being sufficiently regular and homogeneous. Indeed all the then known forms of carbon conductors had the fatal defect of a structural lack of homogeneity On account of this, the resistance varied at certain sections of the filament, and at these very spots, the temperature rose to such an extent that it caused rapid destruction of the filament; this is somewhat similar to the chain which is just as strong as its weakest link

These irregularities in the filament reduced enormously the term of service of any incandescent lamp. Weston tried to solve this difficulty by means of his chemical knowledge. He [illegible]

when he went to visit the gas works to obtain some hard carbon for his Bunsen cell, this carbon was collected from those parts of the gas retort which had been the hottest, and where the hydro-carbon gas had undergone dissociation leaving a dense deposit of coherent carbon.

In this chemical phenomenon of dissociation at high temperatures he perceived a chemical means for 'self-curing' any weak spots in the filament of his lamp. The remedy was as ingenious as simple. In preparing his filament, he passed the current through it while the filament was placed in an atmosphere of hydrocarbon gas, so that in every spot where the temperature rose highest on account of greater resistance brought about by the irregular structure of the material, the hydrocarbon gas was dissociated and carbon was deposited automatically until the defect was cured with the result that the filament acquired the same electric resistance over its whole length. But this invention however brilliant, did not limit his efforts. He had become imbued with the idea that the ideal filament would be an absolutely structureless, homogeneous filament with exactly the same composition and the same section throughout its whole length. He reasoned that such a filament could not be obtained from any natural products ducts neither from paper nor bamboo but that it had to be produced artificially in the laboratory from an absolutely uniform structureless chemical substance. After various unsuccessful attempts he finally secured this result by applying his old knowledge of the days when he used to make collodion. He produced a homogeneous, structureless transparent film of nitrocellulose by evaporating a solution of this material in suitable solvents. As he could not carbonize this film on account of the well-known explosive properties of so-called gun cotton he obviated this difficulty by eliminating the nitrate group of the molecule of cellulose-nitrate by means of ammonium-sulphydrate. This gave him a flexible transparent sheet very similar in appearance to gelatine; this material he called 'Tamidine.' Such films could be cut automatically with utmost exactitude producing filaments of uniform section which then could be submitted to carbonization before fastening them to the inside of the glass bulb of the incandescent lamp.

It is interesting to note here that the modern Tungsten lamp, in all its perfection made of ductile tungsten is after all, the fullest development of the principle of an entirely structureless homogeneous chemical filament. The tungsten-filament can stand much higher temperatures than carbon and this property gives it higher lighting efficiency but the former tungsten filaments of a few years ago which had a granular structure had the same defect as the earlier carbon lamps, namely a non homogeneous texture and correspondent short life.

While Weston was wrestling with all his electrical problems, and more particularly with the construction of dynamos and motors he was handicapped continuously by the clumsy and time-consuming method of electrical measurements which were the best existing at that period. Up till then, these methods had been found good enough for physical laboratories, where the lack of accuracy did not result disastrously in hitting the pocket of the manufacturer or where time—abundant time for observations and calculations was always available. But progress in the electrical industries lagged behind the delay and uncertainties caused by electrical measurements. So Weston was compelled to invent for his own use a set of practical electrical measuring instruments. It was not long before some of his friends wanted very badly duplicates of his instruments, before he knew it, he was giving considerable attention to the construction and further development of these instruments. Just about this time, the electric light and dynamo construction enterprise entered into a new period where they began to develop in large unwieldy commercial organizations requiring public franchises and which had to be backed by vast amounts of new capital. In its boards of directors business men, or financial men and corporation lawyers became paramount factors and eclipsed in importance the technical or scientific men, who, in earlier days, had almost exclusively contributed to the development of the art.

Following his natural inclinations Weston soon abandoned his former business connections in order to entrench himself in a field where individuality, science and technology were of almost unique importance, and which he could develop without the necessity of incurring financial obligations beyond what he could master personally. Thus he dropped his connections with the electric light and dynamo enterprises, and we see him now, heart and soul, in another new industry which he created—the art of making accurate, trustworthy and [illegible] electrical measuring instruments.

In his factory in Newark, N. J., Weston seems to have instilled some of his own reliability and accuracy in the minds of the men and women he employs.

[illegible]

trustworthy measuring instruments nor create reliable measuring methods?

What Stas did in chemistry for atomic weights Weston did for electrical measuring he created radically new methods of measurement and introduced an accuracy undreamt of heretofore. Do not forget that his problems were not easy ones. When the British government offered a prize of $100 000 for the nearest perfect chronometer the problem of a reliable chronometer involved considerably less difficulties and fewer disturbing factors than any of those encountered in devising and making electrical measuring instruments. But here again, even at the risk of monotonous repeating I want to impress you with the fact that the success of the methods of Weston was found in almost every case in the application of chemical means by which he tried to solve his difficulties.

When he took up this subject the scientists as far back as 1884 accepted implicitly the belief that the definition of a metal and a non-metal residue lay in a physical distinction that for metals the electrical resistance increased with temperature, while for non metals their resistance decreased with temperature. This was another one of those readily accepted axioms which nobody dared to refute or contest because they were repeated in respectable text-books. And yet this unfortunate behavior of metals was the greatest drawback in the construction of accurate measuring instruments. Indeed on account of the so-called temperature co-efficient all measurements had to be corrected by calculation to the temperature at which the observation was made. This seems easy enough but it was time consuming and often it is more difficult to make rapid accurate observations of the temperature of the instrument itself. First of all, the thermometers are not accurate and have to be corrected periodically and furthermore it is not an easy matter to determine rapidly the temperature of a coil or an instrument. Moreover by the very passage of the electric current fluctuating changes in temperature are liable to occur which would make the observations totally incorrect. All this led to hesitation and slowness in measurements. Weston wanted to correct this defect but he was told that the very laws of physics were against his attempts. Before he was through with his work he had to correct some of our conceptions of the laws of physics now let us see how he did it.

Weston knew that the favorite metal for resistances was so-called German-silver. Strange to say he was the first one to point out to the Germans themselves that German-silver is a word which covers a multitude of sins and that the composition of German-silver varies considerably according to its source of supply. The result was that he soon proposed a standard copper and nickel- and zinc-alloy containing about 30 per cent of nickel and which had a resistance of almost twice that of ordinary German-silver and a much lower temperature co-efficient. Not satisfied with this he took up the systematic study of a large number of alloys. The first batch which he undertook to study amounted to more than 300 different alloys. Since that time he has considerably increased this number and is still busy at it. Everyone of these alloys he made himself in his laboratory starting from pure materials and controlling the whole operation from the making of the alloy to the drawing of wires of determined size. By long and repeated observations on which many years have been consumed he was able to determine the electrical behavior of each one of these alloys at different temperatures. After awhile he began to observe remarkable properties in some manganese alloys he compounded. He managed to produce an alloy which had 65 times the resistance of copper. But getting bolder and bolder he strove to obtain an alloy which had no temperature co-efficient whatever. He not only succeeded in doing this but finally produced several alloys which had a negative temperature co-efficient. In other terms their resistance instead of increasing with rise of temperature, decreased with increasing temperature. He also showed that the resistance of these alloys depended not only on their composition, but on certain treatments which they undergo for instance preliminary heating. And since that day the physicists have had to bury their favorite definition of metals and non metals. The present generation can hardly realize what this discovery meant at that time. I could not better illustrate this than by reminding you of the fact that in 1892 at the meeting of the British Association for the Advancement of Science where it was urged to found an institution similar to the Deutsche Reichsanstalt Lord Kelvin said in his speech

'The grand success of the Physikalische-Reichsanstalt may be judged to some extent here by the record put before us by Prof von Helmholtz. Such a proved success may be followed by a country like England with very great profit indeed. One thing Prof von Helmholtz did not mention was the discovery by the Anstalt of a metal whose temperature co-efficient with respect to electrical resistance is practically nil; that is to say a metal whose electrical resistance does not change with temperature. This is just the thing we have been waiting for for 20 or 30 years. It is of the greatest importance in scientific experiments and also in connection with the measuring instruments of practical electric lighting to have a metal whose electrical resistance does not vary with temperature and after what has been done what is now wanted is to find a metal of good quality and substance whose resistance shall diminish as temperature is increased. We want something to produce the opposite effect to that with which we are familiar. The resistance of carbon diminishes as temperature increases but its behavior is not very constant. Until within the last year or so nothing definite was known of metals from the fact that elevation of temperature had the effect of increasing resistance. The Physikalische Anstalt had not been in existence two years before this valuable metal was discovered.'

Then followed this colloquy

Prof Von Helmholtz. The discovery of a metal whose resistance diminished with temperature was made by an American engineer.

Prof Ayrton. By an Englishman—Weston.

Lord Kelvin. That serves but to intensify the position I wished to take whether the discovery was made by an Anglo-American an American Englishman or an Englishman in America. It is not gratifying to national pride to know that these discoveries were not made in this country.

The misinformation of Kelvin was due to the fact that after the Weston patents had been published his alloy was called *manganin* in Germany and much publicity had been given to its properties with scant reference to its real inventor an occurrence which unfortunately is not infrequent not only among commercial interests but in technical or scientific circles as well.

No less important was the invention of the Weston cell which in 1908 by the international commission for the establishment of standards of electrical measurements has become the accepted universal practical standard for electro-motive force. Here again this physical standard was obtained by chemical means.

Until Weston's researches on standard cells the Clark cell had been the standby of the electricians and electrochemists of the world as the standard of electro motive force. It required the keen analysis of a Weston to ascertain all the defects of this cell and to indicate the cause of them. Later he drew from his careful chemical observations the means to construct a cell which was free from the defects of its predecessors a cell that had no temperature co-efficient and had no lag.

He detected that the choice of a saturated solution of sulphate of zinc in which was suspended an excess of crystals of this salt was an unsuitable electrolyte and one of the principal causes why the indications of the Clark cell varied considerably with the temperature. It is true that this could be obviated by placing the cell in a bath of constant temperature. But this involves new difficulties due to the proper determination of the real temperature. Furthermore there is always a lag in the indications due to the fact that at varying temperatures it requires a certain time before the solution of the salt has adjusted itself to the co-efficient of saturation for each newly acquired temperature. By studying the comparative behavior of various salts at different temperatures he came to the conclusion that cadmium sulphate is more appropriate and this was one of the several important improvements he introduced in the construction of a new standard of electro motive force.

Dr Weston assures me that he has succeeded in making his alloys to show only a change of one-millionth for a variation of 1 deg Cent. The metallic alloys he discovered are used practically in nearly all kinds of electrical measuring instruments throughout the world. Weston instruments and Weston methods are now found in all properly equipped laboratories and electro-chemical establishments of the world. On a recent trip to Japan I saw them in the University of Tokio as well as in the Japanese war museum where their battered remains attested that the Russians used them on their captured battleships. I have worked in several laboratories in Europe equipped with instruments said to be just as good as those of Weston but in most instances they were imitations of Weston instruments and it was significant that they kept at least one Weston instrument to be used to correct and compare their national product.

Long Reinforced Concrete Bridges

Reinforced concrete is so rapidly coming into general use that some figures relating to bridges of considerable size of this construction are of unusual interest. According to recent statements the Walnut Lane Bridge, at Philadelphia, has a span of 233 feet, at Grafton New Zealand there is a bridge with a span of 320 feet over the Tiber, at Rome 328 feet, at Largaiais, Switzerland, 330 feet, and the proposed bridge over Spuyten Duyvil Creek, New York, 703 feet.

The Gas from Blast Furnaces—II*

Its Cleaning and Utilization

By J E Johnson, Jr

Continued from SCIENTIFIC AMERICAN SUPPLEMENT No 2040, Page 95, February 6, 1915

With this introduction I cannot do better than quote extensively from Mr Forbes's paper as follows

DUST CONTENT IN GAS

The gas leaving the usual dust-catcher contains an average of from 3 to 4 grains of dust per cubic foot and its further cleaning is accomplished in one or two principal stages depending on the ultimate use of the gas namely primary cleaning and final cleaning In primary cleaning the gas is sufficiently cleaned for economical use in heating hot blast stoves and for raising steam in boilers it has been found that the best results are obtained when the dust content of the gas after cleaning does not exceed 0 2 grain per cubic foot In final cleaning the gas is sufficiently cleaned for use in gas engines and in this case the best practice has resulted when the dust content of the gas after cleaning does not exceed 0 008 grain per cubic foot

Various systems and methods are employed for accomplishing the desired results In modern practice the gas leaving the blast furnace is in practically all cases conducted through down-comer mains and then through a dust-catcher of large capacity and in some cases through two such dust-catchers in series A considerable proportion of the heavier dust is deposited at this stage From the dust-catcher the gas passes to the additional cleaning apparatus through gas mains usually equipped with downtakes and valves for the removal of the deposited dust The mode of treatment from this point on varies considerably according to the opinions of the operators as to the respective merits of various systems

PRIMARY DRY CLEANING

For primary cleaning a separation of the dust without the use of water in other words dry cleaning has been in favor at many plants on account of the ability to thus conserve the sensible heat of the gas which is lost when water is used The fact however should not be lost sight of that the benefit derived from the sensible heat of the dry-cleaned gas is largely discounted by the amount of water vapor in the gas This is especially the case with gas from blast furnaces operating with a high top temperature and using ores and coke containing much moisture existing either free or chemically combined the water vapor affects the efficiency of the combustion of the gas

An additional benefit of dry cleaning lies in the greater facility to handle and handle the flue dust in the dry state than in the form of mud or slime in the wet cleaning processes As before stated the basic principles in practically all of these dry-cleaning systems depends upon a change in the direction of the gas a reduction in its velocity and the separation of the dust by gravity and centrifugal force The various modifications by which this separation of dust is accomplished are all evolved from the so-called cyclone processes developed in Germany about 30 years ago Some of these systems recently developed in the United States are the Brassert-Witting the Roberts, the Kennedy and the Dyblie A description of the Brassert-Witting whirler and of the Dyblie whirler will illustrate the general principles of this type of cleaner

BRASSERT-WITTING WHIRLER

As shown in Figs 5 and 6, the Brassert-Witting whirler consists of a vertical outer cylindrical casing A and an inner inverted tube B which at its upper ends is intergral with the gas main C which takes the cleaned gas away from the apparatus This inverted tube is flared at its lower end D a number of iron or steel bars E are fastened vertically around the chamber F and extend from a point well above the lower edge of the flared end D of the pipe to a point well below the lower edge of this pipe In the lower part of the chamber F is placed a cone G which allows the separated dust to enter the outlet pipe

The gas enters the apparatus tangentially through the flue H and is given a rotary whirling motion through the annular space between the pipe B and the wall of the chamber A On coming in contact with the bars E the dust is caught in the channels between these bars and is held in position by the combined action of centrifugal force and friction As the gas continues to rotate within the annular spaces above mentioned its velocity is gradually increased by the action of the flared end of the receiving pipe until when it reaches the lower edge of the end its velocity is at a maximum On passing below this edge the velocity is constantly decreased the direction of the gas is changed and it passes upwardly through the flared end of the pipe to the outgoing gas main C

The dust which has been caught in the channels between the baffle bars drops vertically into the bottom of the chamber past the cone G and into the outlet pipe, whence it is removed as desired

BRASSERT MODIFICATIONS OF BRASSERT-WITTING WHIRLER

In the Brassert modifications of the Brassert-Witting whirler a sketch of which is shown in Fig 7, the lower portion of E of the casing is larger in diameter than the upper portion B and is provided with a series of inwardly projecting baffle plates F The lower portion G of the casing E is cone-shaped and constitutes the dust-receiving chamber In the bottom of this chamber is a cone H whose function is to direct the dust toward the periphery of the dust outlet pipe Within the chamber I another cone J is located and this cone is provided with a series of baffles, which are arranged as shown in Fig 8.

In Fig 9 which is a further modification, a spiral L is provided for the purpose of directing the flow of the gas The lower end of the outlet pipe is made barrel-shaped The outer casing M in its lower portion N is supplied with the baffles O which, instead of being mounted on the casing are bent inwardly therefrom, thus forming the apertures P (Fig 10) The section N of the casing is inclosed by an outer casing, Q, thus forming the annular chamber R, in which partitions S are placed to prevent whirling of the gas.

The gas is introduced and discharged and the dust is separated in a similar manner to that mentioned in the description of the Brassert-Witting whirler.

DYBLIE WHIRLER

In this whirler, as in most of these types, the separation is accomplished by combined centrifugal force and the action of gravity One of the principal features in this particular whirler is the arrangement in the spiral separater of the entrance and exit openings in substantially the same horizontal plane obviating the necessity of the gas changing its direction of flow at a sharp angle

Described in general terms, this separator consists of a spiral conduit the lower open edges of which connect with the dust-collecting chamber The gas is introduced tangentially and follows a spiral course toward the central axis of the apparatus the spiral conduit being increased in area before the gas enters the central chamber prior to its exit from the apparatus

The dust is separated from the gas by centrifugal force and gravity, and falls through the lower open edges of the spiral into the dust-collecting chamber The central chamber is provided with a small opening at its lower end and connects with the innermost spiral of the spiral conduit

In the accompanying sketches, Fig 11 is a vertical section through the Dyblie whirler and Fig 12 is a horizontal section. The gas enters tangentially from the gas main through the opening A in the shell of the casing, the gas impinges upon the first turn of the

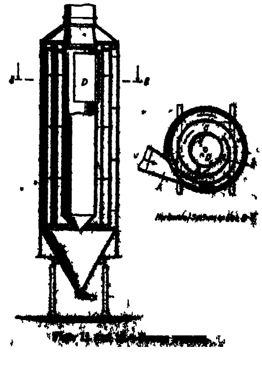

Figs. 11 and 12—Dyblie whirler

* Reproduced from Metallurgical and Chemical Engineering

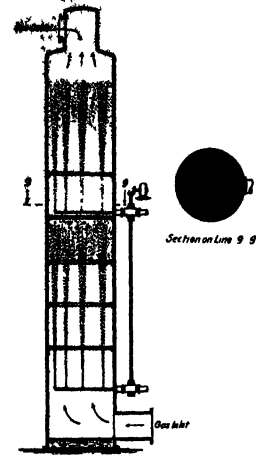

Fig. 13.—Duquesne spray tower

spiral B and follows the turns of the spiral A separation of dust from the gas occurs through centrifugal force, the particles of greatest specific gravity being thrown outwardly and falling by gravity to the bottom of the casing. At the point C an increased area is provided between the spiral and the central chamber which causes a decrease in the velocity of the gas thus allowing a further separation

The inlet A and the outlet D are in substantially the same horizontal plane and this permits the separated material to drop out of the whirling gas and prevents its being caught up in the vortex which happens when a sudden change in the direction of the flow of the gas occurs

A deflector E located at one edge of the opening is provided This is in the shape of a hook which acts to catch any dust which might be carried into the casing and this completes the separating operation

REMARKS ON EFFICIENCY OF DRY CLEANING

It has been demonstrated in practice that dry cleaning by anyone of the systems so far referred to cannot be depended upon by itself to continuously clean the gas from blast furnaces using much fine ore to the degree desired for use in stoves and under boilers the amount of dust remaining in the gas ranging from 1 to 3 grains per cubic foot depending on the working of the blast furnace. Such systems have a value however in removing by simple apparatus and at practically no operating expense a certain proportion of the dust, and so decreasing the duty upon any apparatus installed for further cleaning

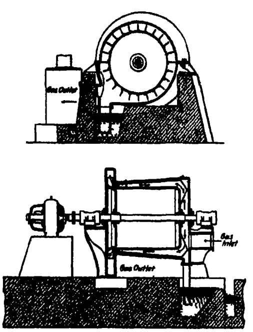
The above remarks on dry cleaning refer in no way to the Halberger-Beth system, recently developed in Germany, which will be treated separately later on

PRIMARY WET CLEANING

For primary cleaning, in Europe in particular a separation of the dust by the use of water has been preferred for many years to a dry separation, on account of the very much greater efficiency obtained in cleaning, and on account of the importance of reducing the water vapor contents of the gas to a minimum, thus allowing more efficient combustion. The cooling and washing of the gas are usually performed simultaneously [illegible] water being used to reduce the temperature of the [illegible] gases to practically the temperature of the incoming wash water. Experience has shown that cooling the gas in this manner, to allow condensation and separation of the water vapor, causes less [illegible] loss of heating efficiency than prevails in [illegible] with [illegible] gas.

[illegible] SYSTEMS

[illegible] washers have been used almost entirely in [illegible] for wet primary cleaning. These consist of [illegible] steel towers fitted with a series [illegible] of hurdles placed at suitable intervals [illegible] These hurdles are arranged in [illegible]



Figs. 16 and 17.—Theisen gas washer

which drip down between the grids and meet the gas coming up the gas being introduced at the bottom of the tower The intimate contact so obtained wets down the dust which is carried with the water to the bottom These Zschocke towers are usually water-sealed and cone-shaped at the bottom and the latest type has a siphon arrangement in either case the dust is readily removed from the bottom of the apparatus

Zschocke towers have been found sufficient to cool and clean the gas to the proper degree for use in hot-blast stoves under boilers and for similar purposes A fan washer into which water is introduced is frequently used as an auxiliary to the Zschocke towers for primary cleaning especially when the scrubbing capacity of the towers is small

A water separator equipped with internal baffles is usually located beyond the washer to allow separation of the entrained water

Zschocke washers are used considerably in the United States and some additional systems have also been developed here for the wet separation of dust for instance the Duquesne spray tower and the Steinbart spray tower The basic principle of these spray towers consists of the creation of a rain or spray by means of suitably arranged nozzles and the gas is cleaned and cooled in passing through this spray

DUQUESNE SPRAY TOWER

The Duquesne tower consists of a shell about 80 foot high by 12 feet in diameter As shown in Fig 13 the tower contains five sets of double screens the sets being spaced 6 feet 10 inches apart Under the first set of screens are distributed seven nozzles the feed water for which is controlled by a valve outside the tower Under the fifth set of screens seven similar nozzles also controlled by a valve outside the tower are distributed just above the range of the lower nozzles

The controlling valves have a revolving core which

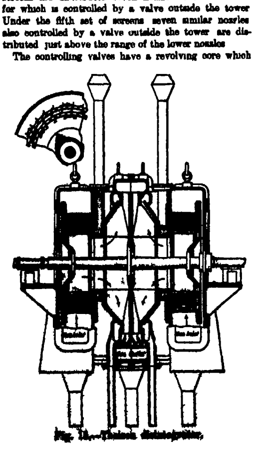


Fig. 18.—Theisen disintegrator.

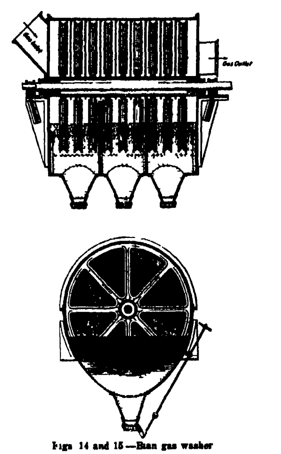

Figs 14 and 15.—Bian gas washer

successively blocks off the opening to the different nozzles thereby temporarily stopping the flow of water and creating an area of low pressure directly above the nozzle When the core has passed the flow of water resumes through this nozzle and sprays the gas which has reached this point The core is revolved electrically at the rate of about 15 revolutions per minute and a 5 horse-power motor is ample to operate four valves which are sufficient for two towers

The screens which are placed above the nozzles break up the water into fine drops permitting intimate contact of the gas and water

In the operation of these towers at Duquesne the gas rises through the scrubber at the rate of 4 feet per second and the water at the rate of 60 feet per second with a head of 35 pounds main pressure The gas is cooled down very effectively the temperature of the outgoing gas being only from 5 deg to 6 deg Fahr above the temperature of the incoming water while the moisture content averages only about 0 5 grain per cubic foot above the saturation point at the temperature of the outgoing gas

BIAN GAS WASHER

The Bian gas washer as shown in Figs 14 and 15 consists of a stationary horizontal steel cylinder through which the gas passes from one end to the other Inside the cylinder there slowly revolves a shaft which carries a number of vertical disks consisting of wire netting of fine mesh The diameter of these disks is very slightly less than the inside diameter of the cylinder and this arrangement necessitates the gas passing through the openings in the screens as it travels through the apparatus The screens to the extent of nearly half their diameter dip into the water contained in a trough upon which the open bottom of the cylinder rests and as the shaft revolves the part of the screens which has been immersed rises from the water with the meshes covered with thin films of water thus allowing thorough contact with the gas as it passes through the perforations

FINAL WET CLEANING

(Some of these systems can also be applied to primary cleaning)

The amount of cleaning accomplished in Zschocke and similar towers and in the Bian washer while satisfactory for stoves and boilers was found to be not sufficient when the gas was destined for use in gas engines and the systems of Theisen and Schiele were developed for this purpose

THEISEN GAS WASHER

The Theisen washer as shown in Figs 16 and 17 consists of a casing lined with a special wire netting within which revolves at high speed a drum carrying numerous fan blades set at oblique angles to the axis of rotation these blades or vanes being so fitted that they form a continuous spiral curve This allows the gas to be drawn in at one end of the casing and expelled at the other end Water is admitted at the side of the casing and is converted into a fine spray by the revolutions of the blades, and the spiral arrangement of these

blades causes the spray to flow in the opposite direction to the gas, which passes through this spray, being simultaneously cleaned and cooled. The dirty water leaves the apparatus by a water seal at the bottom.

The Theisen and Schiele systems of final wet cleaning have for years given very satisfactory results, but are now being gradually superseded by systems requiring less capital expenditure and less operating expense. Most of these systems can be used for primary cleaning as well as for final cleaning, by installing in two stages. The most important of the wet cleaning systems which perform as efficient cleaning with the consumption of much less power and water than the Theisen and Schiele systems, are the disintegrator system of Theisen, the disintegrator system of Schwarz-Bayer, the Fowler & Medley rotary washer, and the Feld rotary washer, while the Halberger-Beth dry cleaning system of filtration through canvas is remarkably efficient in cleaning and is cheap to operate. Following is a detailed description of each of the systems mentioned, together with several other modern systems:

THEISEN DISINTEGRATOR GAS WASHER.

There are two styles of Theisen disintegrator gas washers. One style consists of a casing in which the gas enters by two apertures at the base of the apparatus and is washed by a spray of water in a perforated drum or cage equipped with vanes, the drum revolving within a stationary drum, the gas being drawn through the apparatus by a fan mounted on the same shaft and discharged with the necessary pressure to carry it to the point of consumption. The second style also has the fan mounted on the shaft, but the fan is inclosed within the disintegrator.

The Theisen disintegrator consists of a series of rotary and stationary perforated drums or cages arranged concentrically within one another, as shown in Fig. 18. The stationary drums consists of round bars and the revolving ones of angle bars. The hot raw gas enters the apparatus at the bottom, meets the effluent water and undergoes a preliminary cooling and cleaning in the lower part of the machine. The gas is drawn in counter-current through the series of rotary and stationary drums by means of a fan. The water is converted into a fine spray by the centrifugal action of the rotating drums, and the gas, passing through this spray, is cleaned. The fan is located in the same casing and on the same shaft as the rotary disintegrating drums, the shaft being direct motor driven. Fresh water is introduced into the innermost rotating drums in the form of a finely divided spray.

The cooling and cleaning of the gas and production of the pressure necessary to conduct the clean gas to its point of consumption are all performed in one apparatus and with one motor. It is stated that this disintegrator is an improvement over the former Theisen apparatus, requiring much less power and water, and performing the necessary cleaning of the gas without preliminary towers.

(*To be concluded.*)

"Twilight Sleep" in the Light of Day*

SOME very excellent lay magazines, and some equally good professional ones, have been taking somewhat opposite sides in a discussion of "painless childbirth," according to rules laid down by Drs. Kroenig and Gauss, physicians-in-charge of the maternity clinic, Baden University, Freiburg, Germany.

The treatment is practically an adaptation to obstetrics of Crile's anoci association, that is, it is partly psychologic and partly the administration of drugs to the point of semi-narcosis with the aim of eliminating the memory of pain.

Absolute quiet and very soft light in the lying-in chamber is insisted upon. One hypodermatic injection of narkophen, which is claimed to be less toxic than morphin, is given, and an hour later a first injection of scopolamin into the muscles of the lumbar region. Small doses of scopolamin are repeated at intervals, according to the length of the labor, usually about five doses being given. Advocates of the method claim remarkable results. A few institutions which are properly equipped for the work in the United States have given it sufficient trial to demonstrate that "twilight sleep" *does* act to abolish memory of pain and may be practised without marked danger to mother or child, *but only with every institutional precaution.* Gentlemen who have tried out the German technic do not recommend it as a safe procedure under the usual conditions of a general obstetric practice. Except for the abolition of the memory of pain, and as a luxury to women in confinement, there is, thus far, no sustained claim that the method presents any tangible advantages in the average case of obstetrics.

On the other hand, opponents are severe in their condemnation, claiming danger of the child being asphyxiated, prolongation of labor, and excessive hemorrhage. But perhaps the question of medical ethics involved as regards the kind of publicity employed in exploiting the method had some bearing upon opinion rather sharply expressed.

Despite the fact that medical journals generally were quick to denounce the methods of Kroenig and Gauss, the same journals were equally prompt in commending the made-in-America "twilight sleep," as recommended to be placed in the hands of every doctor who cares to purchase tablets of morphin and hyoscin.

Now, despite many unfavorable reports upon morphin and hyoscin in labor—the journals were full of it a few years ago—there are many physicians using these drugs and claiming good results. They must have a reason for it, just as others have a reason against it. But merely giving morphin and hyoscin is not practicing the "twilight sleep" method; no, not even approximating it!

The fact is that racial differences should modify our obstetric practice, as women of different races present differing problems. No hard and fast rules can be laid down. Some women of neurotic tendencies—pampered, petted, unaccustomed to the hardnesses of life—will welcome the German technic of "twilight sleep." One can readily understand that the method has a legitimate application among a certain class. Also these women should be confined in a special institution, where they can *safely* have the balm of "twilight sleep." And one can understand readily enough that the hard-headed country physician sometimes has cases in which morphin and hyoscin will serve him and his patient. True, if he uses these potent drugs, he should remain a longer time with the patient—charging for his time—so as to be on the safe side, and he should not overdo the dosage. But he should not bluff. Giving a dose or two of morphin and hyoscin is not "twilight sleep," any more than the common but unscientific custom of giving a hypodermatic dose of morphin before anesthesia is "anoci association."

And the blunt fact remains that neither "twilight sleep" nor the administration of morphin and hyoscin in labor is good practice as a routine procedure. Most women need neither one of them. The obstetrical authorities who are opposing these methods are not doing so from mere crankiness.

SURGERY AND ANESTHESIA.

There is a popular demand upon the doctor to "stop this pain!" After all, most of the doses of narcotics we give are given, not because we think the patient needs the narcotic, but because he will promptly go to another doctor if we refuse. This editor may preen himself upon his virtue because he point-blank refuses a narcotic nine times out of ten it is asked for, and loses practice by the many refusals; but the Scotch are good refusers, and it may be bluntness more than virtue. But whatever it is, it saves many a man and woman from themselves. That is part of a doctor's job.

The surgeons are responsible for much of this craze for pain-stopping. Incising a boil for a dollar has given way to the ten-dollar, local-anesthesia surgical operation. "Painless dentists" have the call. Blisters are out of date, principally because they hurt. The man who invents "painless vaccination" will have the antivaccinationists on the run in short order. Women who have hair removed from their faces by the electric needle method are now demanding that cocaine first be applied. It is the pain and annoyance that keeps many women from nursing their babies. Ear-rings have gone out principally because it hurts to pierce the ears. Men are not a bit better. Every headache must be "stopped" by a dose of poison and we must soothe our nerves with several cigars a day. Fie on us! We are becoming soft. And modern surgery is helping along in the craze for "stopping" pain.

So, is it to be wondered at that women are asking why it is that normal labor is being made a matter of elaborate surgical technic and without any form of anesthesia, whereas in other surgical work she is fully anesthetized? Years ago, before a labor was regarded as a surgical crisis, ether was given, and we are being asked why its use was nearly abandoned in the lying-in room.

But physicians know the danger of semi-anesthesia. Maybe we have exaggerated these dangers. Certainly we have devised no way to overcome them. And yet it would seem that, in the supreme crisis of a woman's life, there *should be* a way. Let us try to find it. "Twilight sleep" may be a beginning. So, instead of denouncing it, let us try to find out its weakness. Personally disappointed in all methods of anesthesia or semi-anesthesia we have employed in labor, and not at all inclined to view hyoscin favorably, yet we feel that *a way* should be found, even if it is simply some modification of or improvement upon present methods. Meanwhile, let us be charitable to the physicians who advocate "twilight sleep" and hyoscin. If we discover some better way, then our condemnation will come with better grace.

PAIN AND EUGENICS.

But a few general considerations must not be forgotten. If we are to retain our regard for the well-being of the race at large, we will not allow ourselves to be swept off our feet by the ultra-modern fear of pain and the craze for narcotics. Sex consideration is admirable in its way; but child-bearing is not a matter of ordinary sex consideration, because *the race*, not merely the female sex, is most vitally involved in it.

Of course, it is a trial for women to face child-bearing and its pains. Every proper effort should be made to mitigate these trials. But if eugenics means anything vital to the modern women, she will not act the coward and menace the safe conduct of the important function of child-bearing. She will seek for a remedy, but she will also face the issue whether a remedy is found or not.

* The *Medical Council.*

Fastening Metals to Marble

A CEMENT for fastening metal parts to marble, as in the case of an electrical switchboard, which should be most useful, is given in the *American Machinist*. It consists of thirty parts plaster of paris, ten parts of iron filings, and half a part of sal-ammoniac. These materials are intimately mixed and then acetic acid is added to make a thin paste, which must be used immediately after mixing.

SCIENTIFIC AMERICAN SUPPLEMENT
Founded 1876

NEW YORK, SATURDAY, FEBRUARY 13, 1915
Published weekly by Munn & Company, Incorporated
Charles Allen Munn, President; Frederick Converse Beach, Secretary; Orson D. Munn, Treasurer
all at 361 Broadway, New York

Entered at Post Office of New York, N. Y., as Second Class Matter

The Scientific American Publications

Scientific American Supplement (established 1876) per year $5.00
Scientific American (established 1845) . . . . " 3.00
American Homes and Gardens . . . . " 3.00
The combined subscription rates and rates to foreign countries, including Canada, will be furnished upon application
Remit by postal or express money order, bank draft or check

Munn & Co., Inc., 361 Broadway, New York

The purpose of the Supplement is to publish the more important announcements of distinguished technologists, to digest significant articles that appear in European publications, and altogether to reflect the most advanced thought in science and industry throughout the world.

Aeronautics and the War*

A Review of What Aeroplanes Have Done and of Their Development During the Year

Some time in the future—in the near future, we hope—it will be possible to review the aeronautical activity induced by the war as a whole, and to comment freely upon the facts then known to us. It is impossible and undesirable to do so at present. With the knowledge of what has been done, as possessed at present, we would be in some danger of drawing false deductions. Even now, we fear there is a tendency in some quarters to mistake the aim and object of the military aviator, a mistake fostered by the tendency of the Press to give undue prominence to certain dashing aeroplane exploits.

It is clear enough already that by far the most important duty intrusted to our flying corps is the collection of information concerning the enemy's movements. Time and again, Sir John French and others have paid splendid tributes to this aspect of our aviators' work. It has been definitely laid down as a guiding principle that this collection of information is to be the main object of the corps. Nevertheless, as the commander-in-chief said in a recent dispatch, almost every day new methods for employing the members, both strategically and tactically, are being discovered and put into practice. What these new methods are we will no doubt learn in good time. But for the present we must be content with the knowledge that in addition to collecting information our aviators are endeavoring, very successfully too, to prevent the enemy's airmen doing likewise. As a means for discovering targets for our artillery and for observing the range and directing the fire generally, they have proved themselves invaluable. In addition, it may be gathered that they are being employed to discover the position of our own troops and their movements and report accordingly to headquarters. This is, of course, not a very sensational occupation, but it is one of the results which can be of the highest importance, particularly under modern conditions of warfare. It is only fair to mention here also the admirable but wholly unsensational patrol work that is carried on unceasingly round our coasts by aeronauts of the naval and military wings.

While bomb-dropping has been effective against Zeppelin sheds, supply and ammunition columns, railway stations used by the enemy, and so on, it must not be forgotten that the effect is usually quite local, whereas the aeroplane scout may do work affecting the success of the whole campaign. Other methods of rendering the aeroplane a means of offence against troops have been suggested and tried, one notable case being the equipment of it with a box containing steel darts for discharge against troops in close formation. We have seen and handled two forms of such darts. In one instance, the missile is merely a steel pencil, with a portion of its length fluted by a milling cutter to give it a tail. In the other case, the dart is more elaborate, consisting of a pointed ellipsoidal head, a small rod-like shank and a tail formed of four plane surfaces disposed at right angles. It weighs under 2 ounces, and during its descent probably reaches the limiting velocity of 400 feet to 500 feet per second, so that its striking energy is, say, about 500 foot-pounds. Reports—from German sources, it is true—quite discredit the effectiveness of this weapon.

As for defence against aerial attack or observation, we may tentatively express the opinion that aeroplane is the best reply to aeroplane. Rifle fire from the ground is practically of no avail. Special anti-aircraft guns have been used and have on one or two occasions succeeded in bringing down their prey, but we have received no conclusive evidence to prove that they are an unqualified success. The aerial duel, romantic as it may sound, seems after all to be the most practical method, and in this connection it is highly interesting to note that according to reliable reports our officers seem to prefer the short service rifle and the revolver to any quick-firing gun yet designed or installed. Defence against Zeppelins falls under a different heading. The huge target presented and the slower speed probably render the anti-aircraft gun the best reply, although on this point we have had no real experience to guide us. Reports have been received on several occasions of Zeppelins being attacked by aeroplanes, and in at least one instance we were told that the aviator gallantly sacrificed himself and destroyed the enemy's craft by ramming it. Our readers should be slow to accept these stories as true. Indeed, Garros' exploit was a pure fiction. The operation would almost certainly not attain its desired end in the case of a Zeppelin or other airship possessing a rigid framework and carrying its gas in eight or more separate ballonets. A much more reasonable and less wasteful method for carrying out an aeroplane attack on an airship is clearly indicated in the incendiary bomb.

It is not a little curious to turn back to-day to the "Aviation Memorandum" issued by the War Office in April, 1912. This memorandum, it may be recalled, definitely established the Royal Flying Corps on its present basis. One of the most striking points about it, as now seen, is the extraordinary estimate of the "wastage" likely to occur in war time in the ranks of the corps. The establishment for the expeditionary force was fixed at 182 flying officers and non-commissioned officers, with mechanics, transport, etc., additional. It was assumed that at the end of six months' war the wastage would be 100 per cent; that is to say, that the whole of the original force would be out of action. It has not, we think, been called attention to before, but the fact is that the casualties among the Royal Flying Corps have been remarkably low. We have now been at war for five months, and as correctly as we can discover our casualties have been as follows:

Army:	Killed by the enemy	4
	Killed accidentally	2
	Missing and prisoners	5
	Wounded	5
Navy:	Killed by the enemy	2
	Killed accidentally	3

In addition the naval air service lost two killed and three wounded when H. M. S. "Hermes" was sunk and suffered four wounded in transport and armored motor car work in Belgium. Counting all sources, therefore, the army has lost six and the navy seven of its airmen or mechanics. We do not know what the total aerial force attached to the British army or navy now is, but the *Gazettes* have shown us that since the war began the ranks have been enormously increased. We may doubt, therefore, if the casualties have amounted to more than 2 or 3 per cent. The figure is certainly very much smaller than that for the other branches of the army, so that it appears that the air service during war time is one of the safest to be in. This remarkable and significant deduction is, we may add, confirmed by the reports of some of our aviators, who frankly admit that from the point of view of safety they distinctly prefer flying to occupying a place in the trenches. Knowing all that they have done, their arduous duties, their daring exploits, could there be a finer testimony than this to the excellent construction of our machines and the skill with which they are handled?

In the same memorandum as above referred to some hesitation was manifested in assigning a definite rôle to the naval aeroplane and the organization was left correspondingly elastic. Since then we have progressed considerably. Seaplanes have been rapidly developed, and we have now a Naval Air Service that has been evolved along organized lines from the old naval wing of the Royal Flying Corps. Nevertheless the seaplane or hydro-aeroplane has not taken—or rather, has not been announced as having taken—any conspicuous part in the war so far.[1] This is almost certainly due to the fact that opportunity to do so has been lacking. During the transport of the expeditionary force to France in August airships and aeroplanes—presumably seaplanes—kept watch and ward over the Channel for the approach of hostile craft. It is possible, too, that the aircraft that directed our monitors' fire against the German right on the Belgian coast included some seaplanes. Beyond this we have heard of nothing being done with these craft, although, of course, our seaplane bases round the coast have without doubt been engaged on useful patrol and other work. Our naval aviators have not, however, been idle. They have found a congenial occupation piloting land machines and armored motor cars. The raids on Cologne, Düsseldorf, and Friedrichshafen were all conducted by naval airmen. Still, these facts seem to lend strength only to the suggestion that the naval aeroplane for strictly naval purposes has a much more restricted field of application than its military sister. Indeed, when we read that during the twenty days preceding September 10th our military machines made daily an average of more than nine reconnaissance flights of over 100 miles each—and this may be taken as an indication of their activity since—the inactivity of the seaplane seems to amount in comparison to something approaching failure. In writing thus we wish to express no final opinion, for we are well aware that we have not yet heard all that has been accomplished by our aircraft and that no final judgment can be passed on anything, let alone such a highly complex and technical subject as military and naval aeronautics until the war is well over.

Aeronautics in 1914.

Taking the question of general design, the year has witnessed several fairly wide departures from ordinary practice. While generally standard monoplane and biplane construction has become crystallized around a few departures of detail, there are signs that other possible types of flying machine are attracting attention. The helicopter idea, for instance, is not yet dead, as witness Mr. J. R. Porter's continued activity with his direct lifting parachute machine.

But to confine attention to machines following the aeroplane principle, we may note the construction at the Ponnier Works, in France, of a four-winged monoplane. The two pairs of wings in this machine are arranged in tandem, the front pair having a dihedral angle between them and securing lateral stability, and the rear pair being vee-shaped in plan, as in the Dunne machine, and securing longitudinal stability. Fitted with a 70 horse-power Gnome engine, this machine, under test at Rheims, is said easily to have lifted a useful weight of 1,400 pounds.

As is well known, Mr. A. V. Roe and some others in the early days spent considerable time experimenting with triplanes. Although complete failure did not result, at least in Mr. Roe's case, the idea was generally abandoned. It is difficult at the best of times even now to combine structural strength in a biplane with non-interference of one wing on the other. Still more so must it be in the triplane. Yet as the loads to be carried increase a time will soon come when the biplane formation will result in an impracticably great span and resort will have to be made for purely constructional reasons to the triplane or other formation. It is therefore interesting to note that a successful triplane machine has been demonstrated during the year. This is the Euler hydro-triplane or flying boat, manufactured at Frankfort-on-Main. The top plane of this machine has a span of 46 feet, the middle of 33 feet, and the lower of 26 feet. The three planes, to avoid interference, are very much staggered, the top plane considerably overshooting the middle and the middle the lower. The machine is propelled by a 100 horse-power Gnome engine. We have no record of its performance.

While discussing type variations an historically interesting fact may be noted. On May 6th, 1896, Prof. S. P. Langley of the Smithsonian Institute, Washington, had the satisfaction of seeing his model aeroplane flying for three quarters of a mile against a wind. This machine was of the four-winged monoplane type and was propelled by two screws driven by a steam engine weighing 6¼ pounds per horse-power. A subsequent large-sized copy of this machine, intended to lift a pilot, was constructed, but failed. During the past year an exact duplicate of this machine as preserved at the Smithsonian museum was constructed and fitted with a 90 horse-power Curtiss motor. With a slight reduction in the angle of incidence of the wings and the addition of a hydroplane for starting an American aviator, in September, succeeded in flying it nearly 2,000 yards. Langley's position as a pioneer of flight, sometimes doubted, has thus definitely been established.

Leaving the development of type for the development of detail, we can touch only upon one point, namely, the vexed question of stability. The progress made in this direction has not been as great as we should like to see. It is undoubted that so far as automatic stability is concerned, there is a prejudice against it among pilots, and that this prejudice is hindering progress. They object, it seems, to carrying more machinery than is absolutely necessary, and looking at some of the complicated and delicate devices which have been proposed for attaining automatic stability, our sympathies are entirely with them. They maintain, too, that no device yet proposed secures stability under all conditions, and that at times, notably when landing, the stability must be under the direct personal control of the aviator, with the intervention of the least possible amount of machinery.

The Sperry gyroscopic stabilising device has already been described in these pages, and may be taken as typical of many proposals. Equally typical of another class is the Wright system, to which much attention has been directed during the year. In this the controls are arranged to be operated by a compressed air motor,

[1] These remarks were written before we received the news of the Cuxhaven seaplane raid.

* From *The Engineer*.

The action of this motor is in turn controlled by a vane when the longitudinal stability is upset and by a pendulum when the lateral stability is affected. The use of a pendulum for this purpose has often been proposed, but it is unsatisfactory because of the tendency of the pendulum to swing to its maximum amplitude independently of the magnitude of the displacement to be corrected, and to keep swinging when the machine has been righted. In the Wright apparatus an electrical contact system is employed to correct these deficiencies.

As for inherent stability, progress toward a completely satisfactory solution is still in the experimental and mathematical stage, although, of course, there are many machines in existence which give a fair degree of inherent stability under certain conditions. The ordinary dihedral angle between the wings of a machine is intended to secure partially at least inherent lateral stability. As a development of this, we now have, as in the Curtiss system, a stabilizing disk, with its lateral edges turned up, mounted well above the upper main plane.

The Making of Large Guns

Some Details and Methods of Constructing Modern Weapons

There has been so much in the daily news reports about the "big guns" and what they do, that there is a natural curiosity among a large element of the community to know how these remarkable weapons of modern warfare are constructed. To such the following description of the methods of procedure in building of big guns in England, which we find in the Engineering Supplement of the London *Times*, will be of interest.

From the point of view of the machinist the manufacture of ordnance has three aspects—the large numbers required, the peculiar and special shapes of many portions, and the exceedingly fine degree of accuracy which is absolutely essential. The large numbers required affect the methods of manufacture adopted. There is, of course, an immense difference between the numbers in which the smaller artillery and the relatively few big naval guns are built, between say, the Maxims and the 12-inch or the 15-inch guns. Yet for all alike the shop methods adopted are those which are now generally recognized as processes in which jigging and gaging are essential. When in war a piece of artillery is thrown out of action by the removal or damage of some essential part, it is of the first importance that it shall be renewable without the help of the skilled mechanic. This involves a degree of refinement in measurement which exceeds even that adopted in ordinary engineering works. The highest grade of interchangeable practice is therefore essential to insure the best results; and all the methods which are available to secure those results are freely used—jigs, special drills, boring tools, reamers, cutters, and gages and micrometers. Even when parts have to be finished by hand they are checked and tested by means of fixed gages. Any part of any one type and size of artillery will then take its place in any individual of that type and size.

Again, the peculiar and special shapes of many portions have been the cause of the design of many special machine tools which are used for no other purposes and the details of which are not permitted to be published. Probably one half the tools are either of this character or else they are standard designs greatly modified. In many cases two or more operations are done on the same piece simultaneously. The accuracy required involves not only the jigging and gaging already noted, but also a most elaborate system of testing before the various components are passed to the assemblers and erectors. This work is done in special shops by skilled men who are provided with very delicate instruments and appliances.

METHODS OF BUILDING-UP.

Ordnance in this country is constructed by reinforcing the actual gun tube with rings shrunk on. Two systems are in use, one with, the other without, wire winding. The latter is reserved for the heavier guns and chiefly for naval service, and it affords a very refined method of securing annular increments of tensile strength corresponding as nearly as possible with the stresses which are imposed by the discharge. The wire also reinforces the gun tube so that in most cases the tube will safely endure the enormous stress of 17 tons to the square inch. The steel in the wire is of about double the tensile strength of that in the tubes. The difficulties of shrinking on tubes to secure uniform stress, even though they are divided up into comparatively short lengths, are greater than those of winding wire. If the tube should crack or develop a fault it may still be fired. In the event of an explosion of a shell in the tube the wire winding will prevent grave disaster. A faulty tube can be more readily replaced when wire-wound than when the gun is built up solidly. The illustrations give sections through the two types of guns. The solid gun is seen to be built up of tubes wholly. These are clearly shown, and the jacket, each one shrunk on its predecessor. In the wire-wound gun there may be one or two tubes over which the wire is wound, and the jacket tubes are shrunk over the wire. A bush for the breech plug is screwed into the rear end, which is also reinforced by a breech ring outside.

MACHINING OPERATIONS.

The enormous stresses endured by the built-up guns would not be possible but for the extreme care exercised in the preparation of the steel and in the heat treatment—the annealing and hardening to which it is subjected. The steel is melted in open-hearth furnaces and the metal is poured into solid octagonal ingots. The first machining operation is that of trepanning or boring a hole through the ingot, and is preparatory to the forging. For large ingots the boring bar is rotated, but small ingots are rotated round a bar which does not rotate, but is fed forward. A mandrel is thrust through the hole, while the tube is worked under a hydraulic press to diameter and length. The mandrel is hollow to permit a stream of water to be forced through it to keep the central part cool. Rough turning and boring follow. The largest lathes are used for the gun tubes. The lengths vary with the size and class of gun. The beds range up to 90 feet and sometimes more in length, and height of centers varies accordingly. Generally these lathes have two saddles. They are driven by independent electric motors. Rough boring is done on other machines, the beds of which are long enough to permit of boring from each end simultaneously. Similar operations are performed on the gun tubes and the jackets, but on different machines, each of a length and height of centers suited to the particular work put upon it. In some machines two tubes will be bored simultaneously. An important operation follows, that of hardening or tempering in a bath of oil. The resulting hardness and tensile strength have to pass strict specified tests before any more work is done.

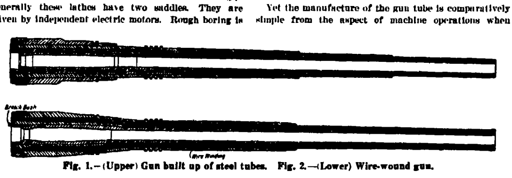

Fig. 1.—(Upper) Gun built up of steel tubes. Fig. 2.—(Lower) Wire-wound gun.

WIRE-WINDING.

From this stage the guns are constructed on one of the two systems named, that of plain tubes and jackets, and that of tubes wound with wire before the jackets are shrunk on. The tube is rotated in a lathe, and the reel off which the wire is wound is mounted on a carriage that is traversed along a bed at the front of the lathe bed proper by means of a screw regulated to synchronize with the rate of revolution of the lathe. The wire is secured at the breech end by being wedged in a recess, after which the winding proceeds along to and fro alternately. To vary the tension that is put on successive layers the wire is nipped between dies of hardened steel pressed in contact by a series of levers and weights adjusted to suit the varying tensions. The tension is diminished in each successive layer. The windings are least at the muzzle and greatest at the breech; in a 12-inch gun they number 12 and 75, respectively. The wire is flat—of ribbon section—about ¼ inch wide by 1/10 inch thick. Its tensile strength is very high, 100 tons to the square inch. A 12-inch gun requires 117 miles, with a total weight of about 13½ tons.

necessary to remove inequalities in readiness to receive the jacket tubes, which are bored to be slightly smaller than the outside of the wire, so that they may be shrunk on. In a tube which is not wire wound the same process is adopted.

When the inner tube consists of two portions, the inner one is slightly tapered on the exterior and also provided with a number of shallow shoulders. The interior of the second tube is bored to correspond with a diameter very little less than that of the one over which it has to be shrunk. It is then heated slightly and the inner tube thrust into it up to the shoulders.

As these shrinking-on operations have to be done with the guns suspended vertically, very deep pits are necessary, partly sunk into the ground and partly built up about it. The heating is effected by gas jets surrounding the jacket. Water taps are provided for use if required for cooling. After the shrinking on is completed the outside is skimmed over in the lathe, and the machining of the keys for the slides of the mountings and the lugs for the breech-block hinge follows.

RIFLING.

The rifling of the bore succeeds, and is done in machines designed for that purpose only, the bar being traversed and rotated to synchronize with the pitch of the grooves. The rotary movement is effected by a pinion on the end of the bar turned by a rack, which is actuated from a templet bar. In long rifling change-gears would be impracticable. In the subsequent examination the accuracy of the bore and rifling is tested by inserting plastic gutta percha. The interior is illuminated with mirrors to detect defects, if any. The exterior is examined while the guns are rotated on roller bearings.

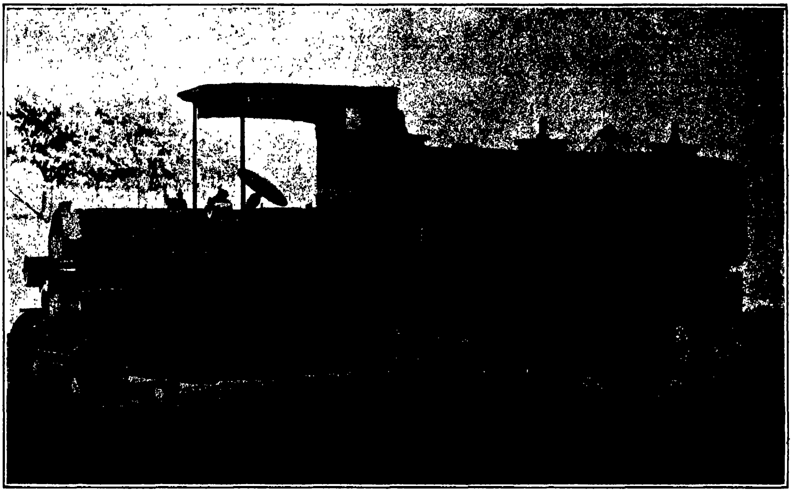
CONSTRUCTION OF THE MOUNTINGS.

Yet the manufacture of the gun tube is comparatively simple from the aspect of machine operations when compared with the component parts of the gun mountings. Excepting in their proportions and dimensions and the differences in wire-winding and building up without wire there is no essential difference between the small and the large gun tubes. All are built up, all are breech-loaders. But the mountings are totally unlike in land artillery and naval ordnance, and in small and large guns. In a Maxim there are about 280 separate parts, entailing about 550 distinct operations done on machines, apart from the fitting. For the 0.303 Maxim about 950 gages are used and the parts—all interchangeable—are within the limit of 1/5,000th part of an inch. On a 6-inch gun there are about 100 parts in the mechanism of the breech alone. The work on the pom-pom gun involves about 770 operations by machine tools done on 400 parts. The amount of tooling entailed on some pieces reduces the weight by one half or more. The lock frame for this gun weighs as a drop-forging 25½ pounds, but only 10½ pounds when finished. Some parts require 27 distinct milling operations, each one being tested by gage.

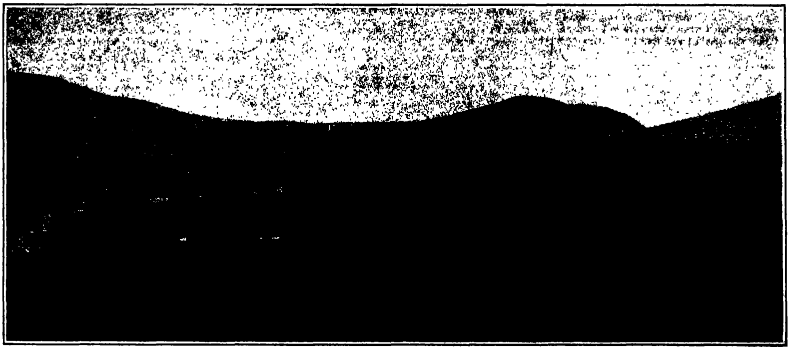
The breech of a gun is a marvelous piece of mechanism, most of the machining of the parts of which is done on special machines. The bush and the block are prepared from forgings long enough for some twenty pieces to be cut from it, and these are hardened and subjected to tests before any actual work is done upon them. Hardness and strength are essential for two reasons—one to offer the maximum resistance to the stresses of discharge, the other to lighten the parts as far as is consistent with safety. All the movements of the block are accomplished by the movements of a single lever in the smaller guns, of a handwheel in the larger, by means of mechanism contained in and about the block, and this detail is a vital element in the quick firing of guns, the importance of which is well understood in modern warfare. Another aspect is lightness.

QUICK-FIRING AND AUTOMATIC GUNS.

All guns now are quick-firing, but relatively few are automatic. The distinction is this—in the first the breech is opened and closed by lever or hand wheel with remarkable rapidity, in the second the energy of the recoil operates the mechanism. In England the Maxims and the pom-poms are the examples of this latter group. In these the breech-block is not screwed, but slides in a vertical plane between guides, a spring and a lever operating it alternately. The pom-pom will fire from 250 to 300 rounds a minute. Each shell weighs about 1¼ pounds and bursts into a dozen pieces. The Maxim will fire 900 rounds a minute, and its projectile weighs 1 ounce. A 6-inch field gun carries a 100-pound projectile. A 12-inch naval gun fires an 850-pound shell, a 15-inch gun one of 1,950 pounds.



Fuel supply tank car for motor transport service.



A rescue car with sides fitted, and a car for carrying parts for replacement.

Auxiliary Military Motor Cars

Various Kinds of Cars That Have Been Developed to Meet Requirements of Armies in the Field

The German army department, in conjunction with the Benzwerke Gaggengau, have designed a number of military vehicles which on account of their special utility are of great importance. Those auxiliary motor cars are kept at the instant disposal of the army in order that in the event of any breakdown of other motor vehicles they can immediately come to the rescue, and they also serve to replenish stores of fuel, oil and water.

Their duties also include keeping the military vehicles of all classes in permanent working order. These cars each comprise a Benz chassis with such alterations and additions as are required for the special purpose for which each is intended. Each machine is driven by a 44.50 horse-power four-cylinder motor, and extra large radiators are fitted, so that even when the vehicles are stationary there is sufficient cooling effect for continuous running of the engine.

There is a motor-driven tank wagon provided for the transport of supplies of fuel, water and oil, and the tank therefore is divided into three compartments. The front and rear compartments contain respectively oil and water, the large central chamber being reserved for gasoline. The gage glasses and a gasoline meter show the amount available in each compartment at any moment, while pumps are fitted by means of which the contents of each compartment are conveyed through flexible hose pipes to the cars requiring replenishment.

As shown in an accompanying illustration, another motor-driven military car has been designed intended for the transport of a complete stock of replacement parts including tires. The tires and larger parts are carried in a central compartment, while the smaller articles are stored in bins on either side of the vehicle. Each bin can be locked, while a special device enables all bins in any row to be closed and locked simultaneously.

There also has been developed another auxiliary motor vehicle intended for carrying bodily a car which may be temporarily disabled, thus preventing its capture by the enemy. This vehicle has an exceptionally long wheelbase and frame to take an extra long platform body fitted with removable sides about 20 inches high. These sides are each fitted with a folding truss, and can be used to form ramps up which a disabled vehicle can be rolled onto the platform. This operation can be performed with little loss of time, as the rescue vehicle is provided at the rear with a winch

(driven by the power of the engine) from which a steel cable is attached to the disabled vehicle. The platform of the rescue car is also so equipped that a crane can be installed and utilized for picking up a vehicle that may be too seriously disabled to be hauled up the ramp as described above.

The military workshop car shown in one of the illustrations is of the greatest importance for the keeping in order of aeroplanes, military motor-cycles and gun carriages as well as other motor vehicles.

As will be noted in the photograph, a complete outfit of machine tools and appliances has been installed on the car, comprising a lathe, shaper, band saw, a smith's furnace and anvil, a machinist's bench, a carpenter's bench, and a grinding machine. At the rear end of the chassis is installed an entirely inclosed direct-current dynamo with an output of 6.6 kilowatts, and driven from the gear box of the vehicle by means of a special shaft and clutch. This dynamo supplies the current to the individual electric motors fitted to each of the machine tools. The shop is also electrically lighted.

It may be stated that the walls of the shop are divided longitudinally and the lower halves are provided with adjustable legs, thus providing additional working space; while the upper halves of the sides furnish shelter. A rail fitted round the top of the roof furnishes additional storage for material. With the equipment here described the various fighting machines of the army may be kept in working condition in the field, when without such travelling workshops much of the military apparatus when once disabled would be useless or have to be abandoned.

The Preserving of Food Products*

MILLIONS of dollars is a lot of money. When invested in perishable foodstuffs, the market value of which fluctuates, and supplying the most densely populated section of this continent, the problem of preserving these products is one of great economic and engineering importance. We will consider only the engineering part of the problem.

Right here, the writer wishes the reader to understand that in this plant uninterrupted service is paramount. To shut down is unthinkable.

Service is sold on a guarantee that the temperature will not vary more than one degree. Suppose the plant fails only for a short time in summer; then the temperature rises and hundreds of thousands of dollars' worth of produce may be ruined. The dealer can claim damages for his loss, and there is always the possibility that, should the service fail and the temperature rise considerably at a time when the market value of the produce is going down, with every indication that it will not rise soon, the dealer might sue, claiming injury to his produce, and thus try to recover a loss or avoid an impending one. Where over 800 customers are served on the street system alone and seventeen large warehouses are filled with perishable goods, as is the case in a large plant in Boston, the damages due to service interruptions would be large.

Service interruptions are as much to be feared as in electric central-station or railway practice, either of which can drop its load and pick it up where it dropped it. A refrigeration station cannot do this. The moment service ceases, the temperature begins to increase, and by the time the plant is again in service, the temperature may have risen so high as not only to damage the goods, but—and here is the point—to require hours to get it back to normal.

Differing from electric or railway station practice, the load is practically constant 24 hours a day for whole seasons. From the viewpoint of overall station economy, this may be desirable, but where real estate values are high and the station's capacity is none too great for the maximum demand, the equipment must go into service prepared for a nonstop run of months. Every feature of operations, every detail of design must be planned to this end, and should an accident occur, the exigencies demand that the crew be capable of getting the machine back into service with the least possible delay, which means that it must be, to a great degree, independent of outside aid except for very exceptional cases.

* From an article on the Equipment and Methods in the Largest Refrigeration System, by Charles H. Bromley, in *Power*.

High Explosives in Warfare*

Interesting Facts Relating to Their Composition and Action

By W. Macnab

AT the present time explosives are playing such a prominent part in the war that the interest and attention of the most peace-loving citizen are necessarily aroused by the terrible results undoubtedly produced, or are more morbidly affected by the tales of the alleged marvelous effects which are yet to be experienced. A few notes on the most important explosives being used in war may therefore be of special interest just now.

The explosives which can be advantageously employed in warfare are by no means the most powerful which the chemist can produce, or which may even be used in civil engineering or mining operations. The military high explosive must be sufficiently insensitive to shock to prevent its being exploded when struck by projectiles, or when submitted to the shock of being fired from a gun as the charge of shell, else it might prove as dangerous to the user as to the enemy. Thus, the nitroglycerine class and many other explosives are excluded.

For many years guncotton, containing a considerable amount of moisture, was largely used for naval and military purposes. In the moist state it is extremely safe, but can be easily detonated when a small primer of dry guncotton is fired in contact with it. The explosive effect is great, and it provided an excellent and safe explosive for military mines and purposes of destruction, and as a charge for torpedoes. It was not, however, suited for use in shells.

The high explosives chiefly being used in the present war for shell-filling are picric acid, trinitrotoluol, and ammonal. Picric acid, with or without the admixture of various ingredients, has been in use at one time or another in most countries under the names of mellnite, lyddite, shimose powder, etc. Until picric acid came into use, black gunpowder formed practically the only explosive used as a bursting charge for shells, and the use of picric acid was a great advance from the destructive point of view, as its explosive power was very much greater. Picric acid, although sufficiently insensitive to shock, has the property of readily attacking metals and forming picrates, which are much more sensitive and liable to explosion. This involves special precautions in dealing with it, and is a disadvantage.

Ammonal is a mixture consisting of ammonium nitrate, trinitrotoluol, charcoal, and aluminium in fine powder. It is very safe, and is more powerful than picric acid, but owing to the hygroscopic character of ammonium nitrate, its chief constituent, it has specially to be protected from moisture, which reduces and, if in sufficient quantity, destroys its power of explosion. It is largely used by the Austrians.

Trinitrotoluol is undoubtedly now the most widely used high explosive for military purposes under the names of "Trotyl," Tritolo," "Trolite," "Tritol," "Trilite," and "T.N.T.," according to the nation using it.

"T.N.T.," as it is called in the British Service, has attained its position by virtue of its merits. It is used in a state of great purity; it is chemically stable and without action on metals. It is unaffected by water, and can be fused and run into shells in the molten state. It is less sensitive to shock than picric acid. Hard blocks of suitable size and shape are covered by electroplating them with a coating of copper, which prevents the blocks from being broken and having their edges chipped. In this form "T.N.T." is used for demolishing bridges, etc. Although not quite so powerful as picric acid, its other advantages make it at present perhaps the best available explosive for military use.

The destructive effect of an explosion is caused by the almost instantaneous conversion of the solid explosive into gases, at a very high temperature, with consequent sudden exertion of an enormous pressure. From the purely disruptive point of view, the composition of the gas produced is not necessarily of importance, the determining factors being the volume of gas, the heat produced, and the velocity of detonation. When, however, an explosion takes place in a confined space, then, in addition to the disruptive or shattering damage, the components of the gas produced may have an injurious effect on anyone having to breathe it.

In the case of explosives for use in civil life, as in mining work, care is taken by adjusting the composition of the explosive that the gases produced shall not have a deleterious effect on the miner. In military operations this consideration does not arise; indeed, it may be maintained the more deadly the effect of the fumes the better.

Picric acid and "T.N.T." are definite chemical bodies, but owing to insufficiency of oxygen are not completely converted into gas on explosion, a considerable amount of carbon being set free. This accounts for the black smoke which is seen when these bodies are exploded.

In the earlier determinations, when explosives which contained insufficient oxygen for complete oxidation of the carbon and hydrogen were fired in a closed bomb, and the resulting gas analysed, it was found that its composition was affected by the density of loading. The higher the density of loading the higher the pressure, accompanied by increase of carbonic acid and decrease of carbonic oxide. Methane, which was absent or only in very small quantities at low densities of loading, increased steadily as the pressure increased. It was, however, recognized that the composition of the gas so found did not necessarily represent the composition at the moment of explosion, for the analysis was made some time after and when the gas had cooled. Consequently reactions had probably been taking place during the process of cooling. Finally, it was thought that the formation of methane was not a real result of explosion, but was due to secondary reactions during the cooling stage. The experimental difficulties of catching and fixing the gases at the moment of explosion were overcome by detonating the explosive in its own volume in a lead or porcelain bomb placed inside a larger evacuated steel bomb. The explosive had in this way to do work in bursting the smaller bomb, and the rapidity of cooling of the gas was thus so greatly increased that secondary reactions practically did not take place. When fired under those conditions, which correspond closely to those which exist when a shell explodes, the gases from ammonal, picric acid, and "T.N.T." were found to contain only small quantities of methane. In addition to carbonic acid, nitrogen, and hydrogen, ammonal contained about 24 per cent, and picric acid and "T.N.T." nearly 50 per cent of the poisonous carbonic oxide. It is thus evident that where shells burst in confined spaces, in addition to the damage caused mechanically, those persons breathing the fumes may be fatally poisoned or seriously effected physiologically.

It has been suggested that the ingredients of shell charges may contain deadly poisons, but it seems improbable that any poison intentionally added to the contents of a shell would retain its toxic properties after the shock and heat of explosion. As seen above, the gases from the explosives now in use may be sufficiently poisonous under certain conditions.

The subject of explosives seems often to create a state of credulity, and to generate extravagance of statement on the part of the non-expert writer rarely effected by other matters. The unknown sometimes becomes truly appalling under his imaginative pen. Even inventors have been known to make wild statements in regard to their explosives! One should only accept with very many grains of salt the sensational statements which have appeared in some quarters as to the weird and deadly effects of recently invented explosives. It is well, therefore, not to have exaggerated ideas of the power of explosives or to be unduly scared by the threat of explosives dropped from Zeppelins. The destructive effect of the large charges which can be fired from the huge howitzers used in the present war is terrible, but explosives have their limits.

While without doubt the damage done locally from the explosion of a large quantity of any explosive which might be dropped by a Zeppelin would be appalling enough, yet, judging from the effects of the accidental explosion of a couple of tons of nitroglycerine during manufacture, its area would be comparatively restricted, and the horrifying suggestions mooted of the coming total destruction of cities by explosives dropped from the sky may be ascribed to the imagination of the over-credulous.

Winter Wireless News Service to the Magdalen Islands.—These islands lie in the middle of the Gulf of St. Lawrence, and the inhabitants have no mail, and hence no newspapers, during the winter. Accordingly the Canadian government is sending a wireless dispatch of 800 words weekly to the clergy of the island, giving the latest news of the war and other events, to be communicated to the islanders on Sundays.

Training for the Municipal Service*

How Public Business is Conducted Efficiently and Without Waste in German Cities

By Clyde Lyndon King[1]

"We have conquered upon the field of battle in war; we are now conquering upon the field of battle in commerce and industry." Such was the watchword which Crown Prince Friedrich gave to Germany at the inauguration of the Museum for Industrial Art in Berlin the day after the treaty of Frankfort, closing the Franco-Prussian war.[2] And Germany has conquered in commerce and industry. One reason for this conquest is that her schools have adopted in effect the standards recently set by the South German Educational Congress: "The state must aim at the diminution of commercial waste by insuring that all occupations, however mean, shall be practiced by men who have been trained to do their work scientifically." After diminishing waste in the occupations, German efficiency is now doing away with waste in the public's business due to inadequately trained and improperly equipped public officials and employes.

Four factors may be singled out as being responsible for the tendency toward sustained and thorough, yet specialized and practical, preparation for municipal service in Germany.

The first of these is the rapid rise in urban populations. In ten years the population of cities of over 100,000 increased 50 per cent. Half of the German population are now urban residents. This enormous increase in urban populations means an increase in public functions assumed by city governments many times greater than the increase in population. This increase in public functions requires efficiency and training of public employes.

Preparation for governmental positions in the state has been provided for in the state universities. These institutions are under the domination of practically the same group of officials that control the state administration. Thus, while state positions are amply prepared for, at least in certain of the universities, though German universities, like many American universities, have been all too slow in adding courses in the political, social and economic sciences, adequate to preparation for the highest public positions, these state institutions do not tend to give the specialization and the emphasis upon municipal service demanded by urban needs. This inadequate training of municipal officials and employes, with its accompanying lack of proper specialization and proper adaptation, caused a demand for local institutions that would offer the training necessary and adequate for municipal employes. This is the second factor tending toward the creation of municipal colleges for the preparation for municipal service in Germany.

The burgomeister and the paid expert advisers in the magistrat were, as a rule, well trained at the state institutions. But no special training was provided for the great rank and file of city employes, the efficiency of whom, after all, decides the skill and utility with which the taxpayer's money is spent. The need for training well every municipal employee, so that there will be no lost motion through inadequate preparation for positions, is the third factor leading toward adequate public training for public service in Germany.

The fourth factor lies in the fact that public service is a recognized profession of dignity and permanence in tenure. The oft-repeated assertion that there are no politics in German city positions is far from accurate, for in many cities an avowed member of the social democratic party could never be ratified for a leading city position no matter what his worth, while a conservative of the landed gentry point of view would be ratified no matter how incomplete his preparation. But in Germany the provincialism characteristic of so many American cities, which brands experts from other cities or states as "outsiders" or "aliens," finds no place. The result is that a public employe with adequate qualifications, who finds himself blocked in one city because of his party affiliations, can look toward employment in other cities. A position once secured, a tenure for life or for a term of 12 or 24 years, is assured, followed by a pension at the end of service. Moreover, promotion is made from city to city, so that there is no limit to the economic returns and social prestige of the public official of competence and skill. Even the burgomeister and all the leading expert advisers in the magistrat are chosen at will from other cities. The salary, moreover, is adequate to attract the best talent, and increases in remuneration follow at specific intervals. The national laws frequently provide that appointees to certain positions shall have stated professional qualifications, but all examinations are qualifying and not competitive. The state examinations merely determine eligibility and within the large list of eligibles the magistrat has full discretion in choosing officials.[3] Probationary periods of service, promotion on the recommendation of superior officers, with due regard to merit and experience, security of tenure, protection against arbitrary dismissal, exclusion of civic employes and officials from all participation in election campaigns, all these features of American civil service find a place in the German system. But the arbitrary provisions characteristic of American civil service, such as that the appointing official is limited in his choice to the three highest, finds no place in the German régime. The result is freedom of choice by an employing official who must have the best talent and get the best results within his expenditures, for pressure of the tax is as keenly felt in German cities as in American cities.

The fifth factor making for the inculcation of efficiency principles in the German municipal service is the fact that the great public utilities such as the street railways, gas and rail waterways, are publicly owned and operated. This means that not only the best paying positions, but also the positions carrying with them social prestige and honor, are within the gift of the state rather than in the power of private corporations. The youth of capacity and training turns, therefore, by preference to the public service.

The technical training required for the municipal expert in Germany is usually afforded by some branch of the regular educational system.[4]

In the first place, there are the great technical universities everywhere maintained by the individual states, in which technical training of the most definite and specific kind can be obtained for either public or private expert work. At the present time there are eleven great scientific universities, the organization of which is under the control of the several states of the German empire. The regulation of industries, however, is within the jurisdiction of imperial laws which have established nation-wide standards as to certain technical experts. These laws, for instance, prescribe the qualifications of persons who wish to carry on particular industries, prescribe the powers and duties of the guilds, and require workers to attend continuation schools where such schools exist. The licensing of certain occupations is under imperial control and attendance at some technical schools is practically necessary for those who wish to pass the required state examinations.

Below the highest technical institutions are two grades of machine trade or mechanical engineering schools,[5] those providing for the training of engineers, constructors, foremen, machine draftsmen, etc., and those of a lower grade which train machinists, mechanical draftsmen and technical officials of middle rank and others preparing for positions that require a less highly developed technical ability. To both these classes of schools are often added Sunday and evening courses, open to workmen who cannot afford to give up work entirely and attend school.

But general school training can not make the efficient employee. There are at least two other prerequisites. The first is specific preparation of a kind that could not be expected in a general university, and the second is particular training for those who are employes and officials in municipal service. To meet these two needs a number of strictly municipal institutions have sprung up in Germany. These schools include the special training schools for employes of certain departments, such as the training school for policemen and the college of town planning in Berlin.

A definite movement for local municipal colleges is on foot in Hamburg, Frankfort-on-Main, Cologne, Dresden and Posen, and the small towns of Altdorf, Willenberg and Helmstedt, all three of which had their own universities in the past and want them renewed.

Cologne has opened an academy whose purpose it is to rescue municipal government from academically trained doctors of law. The curriculum includes definite instruction in social politics, in housing and land questions, in the labor problem, in municipal law, in municipal taxation and finance, in public charity, in care for children, in statistics, in school law.

The work and functions of these new universities can best be expressed by a special study of two of them rather than generalized comment on all of them. For this purpose are chosen the Akademie fur kommunale Verwaltung zu Düsseldorf and the Erste Preussische Verwaltungs-Seminar zu Ascherslében.

The purpose of the academy for municipal administration in Düsseldorf, opened for work in the autumn of 1911, is to strengthen and broaden the knowledge of and to offer a scientific and practical training to municipal officials, and to give business-like, scientific and practical education to persons intending to enter the municipal service. A survey of the courses offered and the methods employed indicates that the academy is primarily an institution for the further training of the higher municipal officials.

The courses offered include the following subjects: Rights of taxes; constitutional rights; governmental rights; the police power; social questions; school and sanitary administration and legislation; insurance law; finance; economics; political science; sociology; the resources of the country; national economy; the lawful rights of government; the organization of city, state and nation; efficiency in government; the science of finance; money and banking; municipal utilities; statistics; building regulations and administration; the cultivation of prosperity and of refinement; the labor question; relief of the poor; business law; practical work in administrative law; municipal finance, constitutional law; taxation law, criminal law and procedure; the poor law; the science of work in business; labor union laws and their interpretation; criminology, and bookkeeping.

The analytical, practical and thorough character of the courses offered may be gleaned from the content of selected courses. Thus the course in the science of law includes the foundation principles as to the rights of citizens and the rights of officials; purchases, leases, deeds and their characteristics; indemnity obligations of the community; earnings and laws of properties; real estate law, rights of mortgages, the authority of parents and the power of the respective governments as guardians; the rights of associations and of business; commercial law; the foundation principles as to state, rural and city administrative law; the constitution of the state of Prussia, the Imperial constitution, the rights of administrative organs of government, the police power and the general position of the police, including the safety and sanitary police. The course in taxation law includes discussions of the various kinds of taxes, such as professional and occupation taxes; concessions; beer, dog, amusement and other indirect general taxes; double taxation; the increase in taxes and the value thereof; the relation between city, district and provincial taxes. Insurance law includes a history of public insurance, the details as to sick, accident and invalid insurance, the relation of the insured to each other. The course in statistics includes discussions as to the nature of statistics, statistical methods, technique in presenting statistics, the principal province of governmental statistics, etc. Thoroughgoing courses are offered in national economy with special application to the protection of properties and the development of new industrial opportunities. Corrupt practices and efficiency in government are likewise taught, as are the cultivation of prosperity in the different communities and the [illegible]

* Abstracts from a paper prepared for presentation at the annual meeting of the American Society of Mechanical Engineers.

[3] "Government of European Cities," W. B. Munro, p. 178.

[4] German schools can be divided into the following two classes: (a) State institutions: (1) Those which are supported entirely by the State, and (2) those for which private corporations furnish a share of the cost; and (b) local community institutions, either pure community institutions or those to which either the State or local organizations contribute. There is a third class of institution, supported by associations and unions, which is not carried on for gain, but which requires considerable financial assistance from both the State and the city.

[5] The higher of these requires greater academic preparation and a longer course of study. Into the second will be admitted those without a complete secondary education but who have, at least, one year of practical training. The Nehere Maschinenbauschulen is a real secondary technical school, the condition for admission being the completion of the six years' course in the academic secondary school, together with practical work in shop or factory for a period of two to three years.

tional programme for industrial supremacy. In the course germain to pure water for the city are given complete geological data. In short, the courses include minute, reliable, thoroughgoing investigations into the legal, social, economic, political, industrial and even geological ramifications of the municipal official's duties and responsibilities.

Quite in contrast to the Düsseldorf academy, which trains primarily the higher officials, is the Seminary for Public Officials at Aschersleben which offers a one year course preparing primarily for the one year probationary service by the middle and lower classes of public employes, and for promotion from one grade of service to a higher grade of service. The duration of the course is one year. The institution is administered by the magistrat of the city of Aschersleben. The courses offered include jurisprudence, administrative law, the science of taxation, political economy, social administration, the administrative courts, the budget, the treasury, accounting, bookkeeping, stenography, typewriting, arithmetic and German. The student is drilled so that he can hunt up and understand the decisions of the civil and administrative courts. The instructors are employed teachers and the public officials of the city of Aschersleben.

The need for further specialized training in America is to be measured by the extent to which existing educational institutions are meeting the rapidly rising demand for well-trained public officials who can look to permanency in the public service. The rapid adoption of commission government so that to-day it is applied in 406 cities with a population of 7,881,987, the adoption of the city manager plan of city government in 12 cities with a population of 229,062, the rise in the demand for sanitary experts, for engineering experts, for experts in marketing, in pure foods, in accounting, in taxation questions, and in the other fields of expert service in city, state and national life, the increase in the municipal ownership of public utilities, all these mean a rapid increase in the actual number of experts in the public service which in turn must mean greater permanency and better training for the public service.

The universities of our country are already doing a splendid work in providing for the public service. A large number of state scientific bureaus are located at the universities, such as public health laboratories at the Universities of Wisconsin and North Dakota, experiment stations in agronomy and animal husbandry, dairy husbandry, horticulture and botany, such as in the University of Illinois, experiment stations in engineering, such as in the University of Missouri, and testing bureaus, such as those at the University of Cincinnati. In the universities of Wisconsin, Oregon, Texas, Washington, California, Harvard and Cincinnati are legislative reference bureaus, which collect and compile information on matters pertaining to municipal legislation, public works, finance, sanitation, education, bibliographies, and statute-making and interpretation. Through the activities of the Committee on Practical Training appointed by the American Economic and Political Science Associations, our universities are beginning to make an extended use of the agencies for practical training available on every hand, such as the practical work by graduate and well-equipped undergraduate students in tax, railroad and industrial commissions, investigating boards, state boards of public affairs, city departments, boards of health, finance commissions, bureaus of municipal research and the different federal agencies in Washington. These laboratories are being and can be made, to an increasing extent, of as definite value to the students in politics, economics and sociology as the splendidly equipped scientific laboratories in the university buildings. All of the various universities now offer courses in constitutional law, in municipal government and allied subjects. University faculties are being called on extensively for practical work.

The University of Texas, with a large number of small cities round about, though with no large municipal laboratories at hand, such as are available in the largest cites, is planning for a department in municipal administration. New York University has a division of public affairs organized in 1912. The plans for this division include a course for graduate students which will give them an opportunity to conduct original research in problems of municipal government under the direction, not only of the faculty of the division, but also of the faculty of instruction and of permanent members of the administration of the city of New York. Moreover, tentative plans are under way for a system of administrative work for graduate students. This plan involves the assignment of two or more students to the same position, at which they will work in turn. Each will thus have time for college and class work, and at the same time will have an opportunity to get actual experience in public administration. There are, of course, only a limited number of positions in the city departments that can be handled in this way.

The University of Pittsburgh is making a special effort to be of service to the commonwealth and to the community, especially in its School of Economics which provides, through its departments of government and citizenship, an intimate understanding of the rights, duties and responsibilities of citizenship and of the functions and activities of government, municipal, state and federal. Students get special training for public service in commissions and administrative bureaus of various types, and in such semi-public organizations as trade and publicity organizations, bureaus of municipal and social research, and other civic and commercial bodies. In the University of Pennsylvania, students in certain courses, such as the course in municipal government, have been and are being assigned definite practical problems to be worked out through the various public bureaus, departments and public officials in the city. The University of Utah undertakes to disseminate through printed bulletins information that will be of service to the state.* The University of Cincinnati is a purely municipal institution which is relating itself in every way possible to the actual problems of the community and of the state. Thus in the department of chemistry of the engineering college is the bureau of city tests which analyzes, examines and estimates the value of all materials submitted by the municipal engineer or the purchasing agent of the city. The department of social science coöperates in social service with public institutions, such as the juvenile court, in investigations, service, etc. The department of psychology has been conducting some interesting work throughout the years past in regard to backward and deficient children in the schools. In this way its work is linked definitely with public school work. The professor in charge of the department of political science is also in charge of the municipal reference bureau at the city hall, which collects information, makes investigations and reports for the city. The college of medicine coöperates with the city hospital, contagious wards, the various clinics, etc. The engineering college coöperates with the city engineering, waterworks, street, sewer and bridge departments, in coöperative teaching, testing, reports and research work. The college of commerce coöperates with the banks of Cincinnati, though their committee, in collecting statistics and reports. In addition to this there is definite service by the individual professors. Students of such an institution necessarily get both the atmosphere and the positive knowledge of great value in their later service for the public. Space forbids the enumeration of other work in other institutions. Our colleges and universities are thus doing much toward practical training for the public service.

Thinking Animals[1]

About ten years ago it became known that "Clever Hans," an Arab stallion owned by a Herr von Osten in Berlin, was able to answer arithmetical and other questions, tapping out the reply with his fore-foot. Notoriety led to heated controversy, and the appointment of committees to investigate. The second of these, under Prof. Stumpf, resulted in Pfungst's book explaining everything in terms of signals consisting in slight movements made unconsciously by some person present knowing the answer. This seemed to have solved the problem finally until the appearance of Krall's book in 1912. The author, a wealthy jeweler of Elberfeld and friend of von Osten, had after the latter's death continued to experiment, obtaining results which, he claimed, refuted Pfungst's explanation. This claim found support in a report signed by the zoologists, Kraemer, Sarasin, and Ziegler, asserting that signaling was excluded since correct answers were given even when none of the human participants was visible to the animal. The opinions expressed on Krall's book vary from that of Prof. Dexler—"a shameful blot on German literature," to that of Prof. Ostwald, who foresees that it will "as clearly mark the beginning of a new chapter in the doctrine of man's place in nature as Darwin's chief work did in its day."

As to the problem itself, a definite solution could result only from a free and impartial testing of the animals; as it is one can only indicate probabilities. Intentional deceit is almost certainly too simple an explanation, and is in any case inadequate. On the other hand, the probability of obtaining correct answers by chance has been underestimated in view of the number of unsuccessful attempts and the greater frequency with which certain numbers occur. Very much must be allowed for this and other weaknesses of testimony, the demonstration of which has been one of the successes of applied psychology, but which, as every newspaper now shows, are seldom given weight in practice. They particularly affect some at least of the would-be crucial tests. Nevertheless much remains, of which the following main explanations have been offered.

The answers are evidence of mathematical intelligence. This, although a highly developed "number-sense" has been found in persons of low general ability, and even in the feeble-minded, conflicts with all that we know from other sources about the animal mind. Detailed scrutiny of Krall's account of his teaching shows that the problem often *could* not have been understood from his exposition. Again, the correcting of a single false figure is done quickly and certainly, as might be expected if signals were being given, since these would be facilitated by concentration of the signaler's attention; if the errors are mistakes of calculation it is odd. Finally, the inability of the animals to prove their understanding by action, compared with their eloquence in the language of taps, is extremely suspicious.

The answers are due to memory. The horse's memory is, no doubt, excellent for some things, and the theory has advantages, but also serious difficulties. To associate eight taps with one symbol and nine with another, the horse must be able to distinguish the two series. But it seems probable that animals cannot distinguish numbers beyond four or five. Rothe trained his dog to come only at the fifth whistle—but this only if the whistles were at regular intervals: his horse would take four lumps of sugar in preference to three, but confused four and five. Again, the horse's eye, while very sensitive to movement, is probably unsuited to the clear perception of complex visual forms such as written numbers, and, as a matter of fact, the animals seem to attend to the questioner more than to the blackboard. Finally, the mistakes in cube root, etc., questions strongly suggest the use of tips.

The animals are responding to unconscious signals. Krall claims to have refuted this by "ignorant" experiments, but these are relatively few and seem to have some weak spot. Thus Mackenzie reports that Rolf, the Mannheim dog, described a picture on a card held so that the holder could not see it; unfortunately, the picture was a red and blue cross, and there is reason to think that dogs are nearly color-blind. Nevertheless, the fair number of "peep-hole" experiments and the case of the blind horse, Berto, seem to stamp as inadequate Pfungst's theory of *visually* perceived movements. Yet no other mode of signal seems sufficient for all cases, while Hacker did actually get answers by moving his foot. Again, it is unlikely that the many individuals who have obtained answers should all make precisely the same unconscious movements. These difficulties disappear if we suppose the animals not to be blindly reacting to one specific stimulus, but to be interpreting more or less intelligently a general type of unconscious emotional ideo-motor expression—movement, variation of respiration, etc.—possibly always complex and varying with the individual and occasion. Both horses and dogs are notoriously sensitive to shades of emotional expression, and recent work by the Pawlow school indicates that dogs can hear sounds so faint as the beating of the heart. It is true, any theory of unconscious signaling presents difficulties. Units, tens, etc. are tapped with different feet; the spelling of verbal answers is phonetic, and *spontaneous* utterances are recorded, including a letter dictated by Rolf! Can the subconscious be credited with so much? The solution, if it ever comes, can scarcely fail to illuminate, if not the animal mind, at least that of man.—From *Nature*.

A Military Wireless Outfit

Wireless communication is destined to play an important part in warfare, and undoubtedly is doing so to-day, although comparatively little is heard of it so far. In this country the Signal Corps of the Army has recently acquired an unusually complete portable wireless outfit, which is believed to be the most powerful of its kind. The apparatus is mounted on a motorcar chassis and can be set up complete and in operating condition in as short a time as twelve minutes. Under favorable conditions, the apparatus has a sending radius of up to 800 miles. Messages from points 2,500 miles distant have been received. The generator which furnishes the current is driven by the same motor that propels the vehicle. Antenna of the umbrella type are used, the mast, which is in nine sections, being 85 feet in height.

---

* Some of these bulletins recently issued include discussion of the following subjects: Tests of brick; the construction and maintenance of earth roads; the economical design of reinforced concrete; measurement of flowing streams.

A German field outfit for X-ray treatment.

X-Ray Work in War

Developments in Practical Applications as Now Used in the Field and in Hospitals

By the Berlin Correspondent of the Scientific American

THOUGH X-ray work has, even in normal times, become so valuable an aid to the medical practitioner that no up-to-date hospital can do without it, it is even more useful and necessary in warfare. Whenever, for instance, the shape and position of a projectile in the body of a patient are to be ascertained, Roentgen photography will quickly give all the desired information; if injured bones, and especially the splintering so frequent with bone fractures (shot fractures), are to be examined, it again proves the one safe guide. Roentgen photographs are nearly always welcome if the perforation made by a bullet has such a direction as to suggest the hypothesis of a bone lesion. The photographic plate in many cases shows the lesion to be much more serious than would otherwise have been supposed. In connection with the further checking of the treatment—in ascertaining, e. g., whether displacements of the bone ends have been adjusted by the dressing, repeated X-ray examination is of the highest importance.

It is true that X-ray work in its primitive form would have been of little use on the theater of war; but so many improvements have been introduced of late years, the technicalities have been so highly simplified, that even the ordinary practitioner will find no difficulty now in handling an X-ray outfit. Transportable apparatus allows the Roentgen ray to be readily employed everywhere in the field, even in temporary infirmaries. A particularly valuable feature is that patients submitted to a Roentgen treatment will suffer no pain or discomfort.

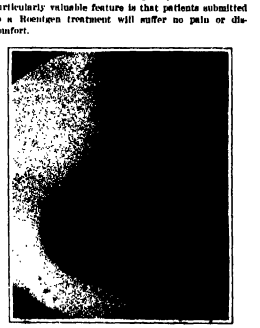
The apparatus serving to generate the rays may be of the most different types. They either consist mainly of an induction coil and interrupter—the active rays being produced by a rapid succession of alternate current impulses—or of a rectifier converting an alternate current into pulsating direct current, that is, a rapid succession of high-tension current impulses of constant direction. The latter type of apparatus is not only more simple to operate, which is especially valuable in warfare, but generally more effective, allowing snapshots to be taken in fractions of a second.

In the military hospital founded by Messrs. Siemens and Halske, in conjunction with the Siemens-Schuckert Works, the German Red Cross and the military authorities, there has, for instance, been installed an X-ray outfit allowing instantaneous views with exposures of only 1/100 second to be taken. This hospital, moreover, shows many other striking features, and may be considered representative of the best German practice in military surgery. It is housed in the administration building at Siemensstadt, near Berlin, and comprises in the four stories of its northern wing, four hundred beds in seven large halls and eighteen private rooms. An operation room appointed in accordance with the best modern practice enables even the most extensive surgical operations to be performed, mainly with the aid of X-ray pictures previously taken. By the courtesy of the managers, we are able to reproduce some such views derived from the hospital archives, which will be found most instructive. In another hall there have been installed all sorts of apparatus for electro-medical therapy.

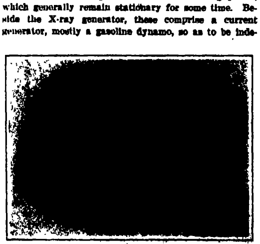
Special transportable Roentgen outfits have been perfected for army hospitals installed at halting places, which generally remain stationary for some time. Beside the X-ray generator, these comprise a current generator, mostly a gasoline dynamo, so as to be independent of any electric installation. While these outfits do not lend themselves to taking instantaneous views, they allow even difficult X-ray pictures to be made with a few seconds exposure in conjunction with a reinforcing screen. The various parts of this outfit are contained in cases carried on automobile trucks, which, as long as the hospital remains at a given place, can be utilized for the transport of wounded soldiers. Special type of X-ray outfits have been developed for ship hospitals and hospital ships.

So large a number of pieces of electro-medical apparatus have been lately adopted that they cannot possibly be left out of account in a discussion of X-ray apparatus, the more so as they are directly or indirectly the outcome of the latter, and serve as efficient auxiliaries in Roentgen practice. Foremost among these should be mentioned the diathermic apparatus which by the application of high-frequency currents produces some sort of internal heating of the body. Diathermics is used with advantage in the treatment of neuralgic, rheumatic and gouty complaints; it is most valuable in the after-treatment of bone lesions, and its anesthetic effects are remarkable.

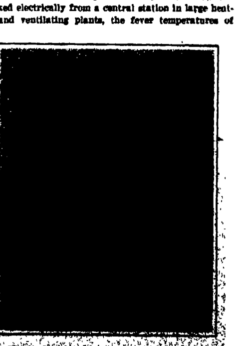
Electric temperature measurements are used in a rather unusual way at the Siemensstadt military hospital. The same as temperatures are determined and checked electrically from a central station in large heating and ventilating plants, the fever temperatures of



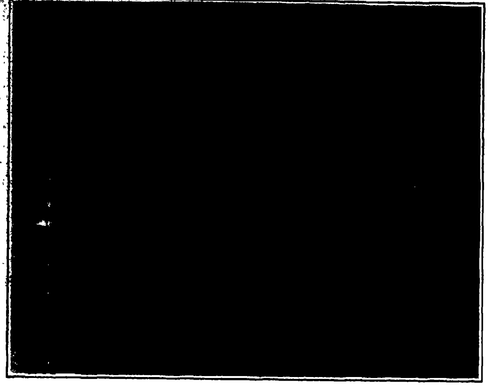
X-ray of a wound in foot caused by rifle bullet.



Siemen's tungsten X-ray bulb.



Triple [illegible]



Recording fever temperature of a patient during a test of the effect of a sudatory.

patients are here recorded electrically and signaled to a central post. This, of course, affords a great advantage over the usual method of determining the temperature of the patients two or three time a day; in fact, the clear record of the course of temperatures thus obtained not only assists more efficiently in making a diagnosis, but affords some useful data in gaging the effect of medicaments or therapeutical methods.

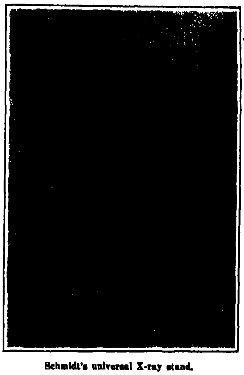
Apart from the Roentgen apparatus proper, we should mention the accessories without which no sharp views could be taken. The same as in ordinary photography, a stop is placed in front of the objective, to keep off any lateral beams of light and thus to improve the definition of the picture, it is a good plan in X-ray work to screen off any secondary rays which are bound to impair the quality of the picture. The "compression" stop devised by Prof. Albers-Schönberg allows any part of the human skeleton to be reproduced with the utmost accuracy. Another type is Dr. Bucky's "beehive" stop, which intercepts any secondary rays produced inside the body before these are allowed to strike the projection screen or photographic plate.

For radioscopic and radiophotographic work on standing, sitting, or lying patients there have been devised quite a number of folding stands which will keep the body straight, in addition to avoiding displacements and insuring an accurate adjustment of the body.

The X-ray bulb itself, of course, is of the highest importance. Each military hospital ought to be equipped with quite a number of bulbs adapted for various purposes, part for radioscopy and part for X-ray photography. According to the special purpose each bulb is intended to serve, the vacuum must be more or less perfect; the higher the vacuum, the "harder" or more penetrating will the X-rays be, and *vice versa*.

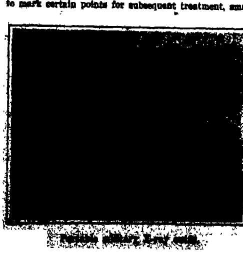
A minor, though useful, accessory are the sand bags, which allow the patient to be installed most comfortably in any position.

The ascertaining of foreign bodies (projectiles) in the patient's body is generally limited to the upper extremities, neck, thorax, and to the lower extremities from the knees downward, as well as the skull. In order to mark certain points for subsequent treatment, small lead labels are glued to the skin, or the places in question are spotted with a blue pencil, ink, or tincture of iodine. In order accurately to ascertain the positions of a projectile in the body, two views—in planes vertical to one another—are, of course, required. A safe diagnosis for bone fracture can hardly be made on the strength of radioscopy, X-ray photography being generally indispensable in this connection. For checking the fracture in the plaster dressing, as well as for the diagnosis of sprains, radioscopy, on the other hand, mostly affords sufficient data to allow a safe conclusion to be arrived at.



Schmidt's universal X-ray stand.

Another point to be mentioned is that parts generally invisible (e. g., in examining the stomach and intestines) can be made visible by administering to the patient what is called a "contrast" meal, comprising some heavy metal salts, such as bismuth, impervious to X-rays.



Portable military X-ray outfit.

Wireless Telephony*

DURING the early part of March Mr. Marconi joined one of the Italian war vessels at Augusta attached to the squadron commanded by H.R.H. the Duke of the Abruzzi, and for several days he carried on experiments in wireless telephony with most satisfying results. During the first day radio-telegraphic communications were received from Rome over a distance of 366 miles, from Vienna over a distance of 600 miles, and from Clifden, in Ireland, 1,750 miles away. These communications were made during the day, and new high resonance receivers with photographic register repeaters were employed with excellent results. Experiments in wireless telephony were carried out on the following day between several vessels lying at anchor at a distance of one kilometer with great success. The wireless telephone experiments were continued on the third day, this time between two warships on the high seas, and the reception was consistently perfect over a distance of 30 kilometers. On the fourth and last days successful telephone experiments were again carried out, communications taking place with very limited energy between vessels on the high seas, 70 kilometers (45 miles) apart. On the last day radio-telephonic communication was constantly maintained for 12 hours, and the continuous working of the apparatus did not cause the slightest inconvenience. The apparatus employed in the experiments is of a new and simple type, and it was Mr. Marconi's desire that it should first be used on the warships of the Italian Royal Navy.

A new transmitting apparatus for wireless telephony was invented by Herr L. Kuhn. The microphone current is passed through a winding on a soft iron core on which is wound a second coil connected with the antenna circuit. The self-induction of the latter coil varies according to the fluctuations in the microphone circuit, and the oscillations in the antenna circuit, therefore, also vary in frequency accordingly. By this means it is stated than an oscillation energy of 8 kilowatts in the antenna circuit has been sufficiently influenced by a microphone energy of only 8.7 watts to effect a proper transmission of speech.

*The Engineer.

Effect of the War Upon Crime

THE Basle *Nachrichten* publishes a summary of the offenses against the Swiss penal code, just before and since the outbreak of the war, concerning which complaints were made to the police authorities. While during July of the present year 269 complaints were made, the number reported for August is only 162, for September 177, and for October 158.

The statistics for 1913 give the following totals: July, 348 complaints; August, 314; September, 306; October, 301. At the close of July, 1914, the number of cases tried by the public prosecutor was about 140 more than for the same period of the previous year, while an inspection of the statistics up to the end of October shows a decrease, there being about 130 trials less than for the year 1913; that is, there was a falling off of about 270 cases in three months.

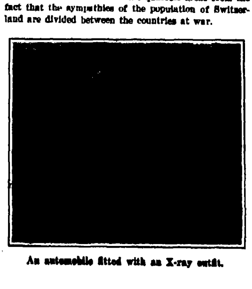
The German journal *Umschau*, in discussing these figures which it quotes, says that one important reason for this striking decline in the perpetration of crimes is that the floating population, from which a large percentage of the lawbreakers is drawn, has been largely reduced since the beginning of the war by removals, summons to the armies, expulsions, etc. The mobilization of the Swiss army has also exercised a favorable influence upon criminal statistics.

The fixing of an hour for the closing of the saloons led to an abatement in assaults, crimes against property, threats, and acts of insubordination. Most interesting of all are the figures concerning the complaints of assaults.

In 1914 the complaints as to premeditated bodily assaults run as follows: July, 28; August, 13; September, 18; October, 17. In 1913 the figures were: July, 37; August, 31; September, 29; October, 28.

In the months of August, September, and October, 1913, there were 9 complaints in regard to acts of insubordination, while during the same period of the year 1914 only a single case was brought before the division for criminal investigation.

In a few cases of brawls the quarrels arose from the fact that the sympathies of the population of Switzerland are divided between the countries at war.



An automobile fitted with an X-ray outfit.

Chemistry of Flaming Arc Carbons*

Their Development and Operation

By Dr. William C. Moore

In an arc struck between two carbon electrodes, very nearly all the light comes from the incandescent electrode tips. In a direct-current arc, the positive crater is larger, and possibly at a higher temperature than the negative crater, and it is this positive crater which is the source of most of the light. Since the crater is merely an incandescent solid, it affords a continuous spectrum. Colorimetric experiments recently made by L. A. Jones and reported by him at the Cleveland meeting of the Illuminating Engineering Society, September, 1914, show that this incandescent crater has about 67 per cent of the daylight value of noonday sunlight. When volt-ampere readings are taken with such an arc it is found that if the arc is strengthened the voltage rises and the amperage falls, and eventually the arc goes out.

If we use as one of our electrodes a carbon rod which has been hollowed out into a cup, and place in the cup some potassium chloride, and again strike the arc, we find that the volt-ampere characteristics are changed and that at the same amperage a much longer arc can be drawn. Casselmann in 1844[1] seems to have been the first to have noticed this fact. As we see, an arc fed with potassium chloride gives very little light; in fact, probably less than the pure carbon arc, as the positive crater is not so bright. This arc has a distinctive color, and, of course, would show, besides the carbon arc lines, the potassium lines in the spectroscope. Bunsen[2] in 1844 seems to have been the first to notice that different materials give different spectra in the arc.

If, instead of potassium chloride, we place a small amount of calcium fluoride in the hollow carbon cup, which, in this as in the previous case, is in the lower positive carbon, we find that the arc length for a given current and voltage is much shorter than for potassium chloride, and longer than for a pure carbon arc; moreover, the arc is intensely luminous, though rather unsteady and liable to go out. On placing a mixture of potassium chloride and calcium fluoride in the arc, we get the combined advantages of a *long* arc, with more intense luminosity than is afforded by either the pure carbon arc or the potassium chloride arc alone. These simple facts form the starting point in the development of the modern flaming arc.

About 1899, Bremer, in Germany, brought out a flaming carbon, with calcium fluoride as the essential light-giving salt. The light afforded by such a carbon is a sensation yellow; the color is more aptly described, however, as "minus blue," as the spectrum of such an arc is very deficient in the blue.

From 1899 to the present the development of the flaming arc has been going on steadily and surely. It is interesting to note that the first record the National Carbon Company has of any work being done by them on the subject was when some ordinary cored carbons flamed and experiments were undertaken to prevent this phenomenon.

Although Bremer produced a carbon which could be burned vertically, for a number of years most of the commercial lamps were "inclined trim" lamps, taking long, cored carbons, which burned under open-arc conditions. A few years ago, however, there was developed a lamp for burning flame carbons in a vertical position, and for these lamps solid carbons have been developed. An interesting point is that the idea of solid carbons antedated the development of the lamps. These lamps generally operate in such a way that a limited supply of air reaches the arc; that is, under "inclosed-arc" conditions. These various types of lamps are doubtless familiar to the illuminating engineers present.

Modern flame carbons may be classified in several ways. From the standpoint of the mechanical structure of the finished carbon, we have cored carbons and solid carbons. From the standpoint of the color of the light emitted by the carbons, we have a major division in which are included yellow flame carbons and white flame carbons, and a minor division including red, green and blue flame carbons, red and green being but little used except for advertising purposes, and blue being used as a source of blue and ultra-violet light for medicinal purposes.

In the major division, calcium fluoride is the chief constituent of yellow flamers, and rare earth compounds the chief constituents of white flamers.

A brief description of the method of manufacture of flame carbons may not be out of place. The first step, of course, is the careful weighing out of the requisite amount of the carbon base, and the proper flame materials for making a "mix." Most of these mixes are rather complex. After weighing, the ingredients are very thoroughly incorporated together and with an appropriate binder—generally tar or pitch or a mixture of these. The "mix" is then forced by means of an hydraulic press into long rods, which after cooling are cut into the proper lengths. These green carbons are then carefully baked in gas-fired furnaces and the temperature gradually raised according to a definite schedule, the final temperature attained being determined by a number of factors, such as the liability of some of the constituents to violatilize, or to react with each other and the carbon.

After cooling in the furnace, the carbons are unpacked, sorted, cleaned and gaged, the latter process consisting in determining the diameter, as but small variations in diameter are permissible; the carbons must also be quite straight. Some solid carbons are electroplated with copper on the holder end to make a better contact between the lamp holder and the carbon. After plating, they are dried and made ready for shipment.

It is, of course, necessary to keep all flame carbons dry, as water may cause reactions between some of the flame materials, or may set up on a carbon-copper cell with some of the soluble or partially soluble salts as electrolytes and thereby destroy the copper coating. Water has another detrimental effect as shown by W. R. Mott,[3] namely to react with the carbon at high temperatures, forming carbon monoxide and hydrogen; the latter may not only accumulate in the lamp housing and cause the lamp to explode when started again, but rapidly conducts heat away from the burning arc and lowers its efficiency.

The manufacture of cored carbons is quite similar to that of solid, except that the carbon base is different, and in forcing the die contains a pin which makes the carbons hollow. After baking, sorting and gaging this core hole is filled with a mixture of a carbon base and the flame materials with an appropriate binder, and the carbons are then dried. As cored carbons are usually very long and of small diameter, a zinc wire is inserted into a small hole parallel to the core hole. This wire increases the conductivity of the carbon. In order to make a good contact with the carbon and the holder, the carbons are "silver tipped"—that is, first copper plated, then dipped into solder, which solders the zinc protruding from the holder end to the carbon. Such a connection is a permanent one, and is far superior to the scheme of simply bending the zinc over at the end of the carbon as the zinc becomes brittle when the core is dried and is liable to break off.

We now come to the question of desirable operating characteristics for a flame arc carbon. First of all, such a carbon should be reliable. It has been pointed out by Steinmetz[4] that after high efficiency is attained, we can afford to sacrifice some of the efficiency for reliability and other desirable factors. As will be shown below, the flame arc is already of high efficiency, hence we place reliability as our first desirable characteristic.

We may consider reliability under the four heads:

1. Constancy of distribution.
2. Constancy of light flux.
3. Constancy of color.
4. Ability to start with cold points after the carbons have been in use.

The length of the arc has a great deal to do with the amount and distribution of light. As the arc lengthens, the voltage increases; it is staced by Hechler[5] that there is a maximum definite voltage for maximum efficiency, that is, some definite arc length gives the most light.

The part that chemistry has had in increasing the reliability may be briefly indicated. It is readily seen that a flame arc which burns brightly part of the time and dimly part of the time can hardly be said to have 100 per cent reliability if all the other factors are high. It may happen that all the flame material is evaporated from a given spot on the surface of the carbon, thereby causing a pure carbon arc for a short time. Such changes, however, are now rare, as a great deal of constructive chemical work has practically obviated this feature. As another factor affecting the reliability of operation of flame arc lamps is the formation of slag on the points or on the lamp mechanism, it is readily seen that the proper proportion of the flame constituents and the right kind of addition agents for preventing such slags are of great importance, and here again we find that extended chemical research has resulted in the development of carbons in which this source of trouble has been largely overcome.

It has been mentioned that the flame arc is of high efficiency. The following figures are from some regular routine tests made in the laboratory:

Lamp	Current	Kind of Carbon	M.H. C.P.	Arc Watts	Watts per Candle
Excello........	A.C.	Cored—yellow....	1,230	363	.29—
Excello........	A.C.	Cored—white....	843	360	.42—
Excello........	D.C.	Cored—yellow....	1,462	445	.30—
Excello........	D.C.	Cored—white....	875	450	.51—
G. E. Type W..	A.C.	Solid—yellow....	700	397	.56—
G. E. Type W..	A.C.	Solid—white	808	394	.49—
G. E. Lynn.....	D.C.	Solid—yellow....	1,181	409	.35—
G. E. Lynn.....	D.C.	Solid—white....	930	431	.45—

The slightly lower efficiencies with the solid carbons are due to the fact that they are used in inclosed lamps, to which the air has only limited access, and so in these lamps there is less oxidation of the carbon and the flame material.

Some work by Henry P. Gage[6] at Cornell University on the efficiency of the arc stream proper may be cited here. This investigator found that with cored yellow-flame carbons the energy radiated as light from the arc stream was 30 per cent of the total energy radiated by it; with the arc stream, from cored white flame carbons 27.5 per cent of the energy radiated by the arc stream was light energy. The entire yellow arc showed six candles per watt radiated, while the entire white arc showed three candles per watt actually radiated.

These values are for the spectral region between 3,800 and 6,800 Angström units, and for alternating current at 13.5 ampere. The following data may be presented as to the life of flame carbons:

	Life in Hours. A. C.	D. C.
Cored, yellow..........	12.0	12.50
Cored, white..........	11.06	11.25
Solid, yellow.........	115.06	125.0
Solid, white........	120.0	96.42

These figures show why the inclosed flame arc lamp is more popular than the old "inclined trim" lamp, using cored carbons.

Having indicated at a number of points the important part chemistry has played in the development of the modern flame carbon, let us now take up in greater detail some of the chemical aspects.

In the first place, the selection of the proper materials for the manufacture of flame carbons is to a very large degree dependent on the chemical properties of these materials. When we consider the carbon base, we find that the chemical behavior, as well as the physical behavior of the various so-called forms of carbon, differs with the type of carbon employed. To use an extreme case as an illustration, we know that the chemical properties of graphite differ greatly from those of lampblack. There are likewise similar differences between charcoal and lampblack, petroleum coke and retort coke. This, in part, accounts for a different carbon base being used for solid and for cored carbons.

To a greater degree than the proper selection of the right carbon base the selection of the right sort of flame material and the right sort of addition agents with this flame material has been a chemical problem. This is illustrated by the fact that to-day we know no better material than calcium fluoride for the main constituent of yellow flame carbons. I do not think I will exaggerate the matter in the least when I say that compounds of every compound-forming element have been proposed as proper substances to incorporate into flame carbons—some of them in all sorts of possible and impossible combinations.

Having selected the right materials, the right amount of each is our next chemical problem. That the candle power depends upon the amount of flame material is well known; more exact information on this subject, however, may be had from the following table, which is from some work done in our research laboratory by

* Paper read before a joint meeting of the New York Section of the Electro-chemical Society; the American Illuminating Engineering Society and the American Gas Institute.

Mr. William R. Mott, using cored carbons in an Excello direct current lamp:

Parts of calcium fluoride by weight.	3	2	1	0
Parts of other salt by weight.......	0	1	2	3
Mean spherical candle-power.......	927	1,058	765	574

As is seen, there is a maximum per cent of each of the constituents which will give the most light. This is true with nearly every substance which may be added to the calcium fluoride, and when we consider that flames contain three or more substances in addition to the main constituent, it is readily seen that the nice adjustment of all these substances to each other presents some very interesting problems. It also explains why so much of our knowledge has been obtained in an empirical way. It is, of course, understood that the maxima for different addition agents do not coincide.

The chemical control of the impurities present in the raw materials is of great importance. Silica, ferric oxide and alumina, as is well known, are common impurities in calcium fluoride, and it so happens that too much of these impurities will make a poor burning carbon. Silica is especially undesirable, as calcium silicate is very non-volatile and so is a frequent cause of slag formation. The analytical difficulties in determinations of fluorine, silica and rare earths in the presence of each other and of carbon are very great.

The unbaked carbon is a poor conductor of electricity. It is also rather friable. In the baking, the binder is coked and the carbon is rendered homogeneous and conducting. This coking of the binder is the chief chemical change in the manufacture of the carbon.

We now have to consider what chemical changes may occur during the burning of a flame carbon, and how these may affect the light emitted from the flaming arc. There are three possible sources of light in the flaming arc: electro-luminescence, thermo-luminescence, and chemiluminescence. We do not know to what extent these three factors affect the light radiation in any one case. We do know, however, that in general there are two types of flaming arcs, (1) those in which the outer sheath seems to be intensely luminous, (2) those in which the core of the arc seems to be more luminous than the sheath. With very few exceptions arcs of the latter type give light of the shorter wave lengths. We have here an arc into which calcium fluoride is introduced, it is a representative of the first type; here is an arc into which chromic oxide is introduced, it is of the latter type. King has recently reported[5] that in a tube furnace almost all of the spectral lines seen in the arc spectrum of titanium appear, so that it would appear that in some cases a large proportion of the light from an arc is due to thermo-luminescence, though all possibility of chemical change was not precluded by these experiments.

Oldenberg[6] has made a spectro-heliographic study of various arcs, with some interesting results. For instance, he concludes that in the sodium arc, lines belonging to the principal series such as the "D lines" are due to chemical reactions between the vapor and the air. Band spectra seem to be of two types: those of the first type are due to collisions of atoms in the high temperature core of the arc. The cyanogen bands always seen in a carbon arc he ascribes to collisions between carbon and nitrogen atoms. Bands of the second type are found in the sheath of the arc; they are due to undecomposed molecules; the bands of the calcium fluoride spectrum are of this type. When we consider that the flaming arc is a miniature electric furnace; that Fremy[7] showed years ago that oxygen converts calcium fluoride into calcium oxide; that calcium oxide and carbon react to give calcium carbide and carbon monoxide, and that the other constituents of a flame carbon may react with calcium fluoride, with the carbon, with each other and the atmospheric gases, we see that it is possible for chemical changes to play an important part in the production of the light of the calcium fluoride arc. Each of the possible substances may play its part in this light emission.

In conclusion, I think we may safely say that the past progress made in the flaming arc art has been due to the co-operation of the chemist, the physicist, and the electrical engineer; the future progress will likewise be dependent upon their combined efforts.

It might not be out of place to point out that the behavior of any one substance in the arc is determined by the conditions surrounding that substance—it behaves according to definite chemical and physical laws; and that our knowledge of these laws for high temperatures is exceedingly meager. On the other hand, once those laws are learned, it will probably be easier to build lamps to suit the carbons rather than to make a carbon to fit any and every lamp. In the extension of our knowledge of these laws, chemistry and especially physical chemistry will play an important part.

Uniformity in Dosage of Radium Emanation*

The Various Forms Employed and Methods of Preparation

By William Jay Schieffelin, Ph.D.

Radium emanation is assuming importance as a therapeutic agent. The Council on Pharmacy of the American Medical Association has listed radium and its emanation among new and non-official remedies; an increasing number of physicians are using the emanation in their practice, and articles and advertisements on the subject are appearing in the medical journals. Since radium and its emanation are becoming recognized as belonging in the materia medica, their production and properties and the standardization of their preparations may be claimed to come within the scope of pharmacy.

Radium is prepared from carnotite (vanadate of uranium and potassium), uraninite or pitch-blende (uranium oxide), and samarskite (columbate and tantalate of uranium and yttrium). Radium has an atomic weight of 226, and resembles barium in its chemical properties.

In its characteristic property of radioactivity radium is sublimely superior to its environment, whether in its natural minerals or isolated from them, and in all of its chemical compounds it is constantly emitting alpha rays and emanation at a uniform rate, and there is no known way of influencing or halting this activity, which is not affected by the extremes of heat and cold, by pressure or the strongest reagents. This radioactivity shows the energy which results from the disintegration or transmutation of radium into elements of lower atomic weights.

A milligramme of radium expels 136 million separate alpha particles per second, which are made visible in a spinthariscope. The alpha rays emitted from one three thousand millionth of a grain of radium can be detected by the gold-leaf electroscope. The rays are given out uniformly in all directions in the form of continuous volleys of tiny projectiles traveling at a rate of 12,000 miles per second. Their range is nearly three inches in air and many yards in a vacuum. They are not penetrating, being absorbed by thin sheets of aluminium, paper or glass. Only a small fraction of the alpha particles is set free, unless the radium salt is spread out so as to present the largest possible surface.

The emanation is a gas, which, in turn, steadily disintegrates into alpha particles and radium *A*, from which in the same way come radium *B*, *C*, *D*, *E*, and *F* in succession. It is from these products, especially radium *C*, that the beta and gamma rays are given off. The beta rays are electrons of negative electricity, the same as the cathode rays, except that the velocity of the beta particles is much greater, approaching the velocity of light, 186,000 miles a second.

The gamma rays are not considered to be particles of matter, but are waves in the ether similar to the X-rays. They are far more penetrating than the alpha and beta rays, and used in the external application of radium in cancer, the others being easily excluded by thin metal filters.

The emanation has an atomic weight of 222, and a characteristic bright line spectrum. It belongs in the group of inert monatomic gases with helium and argon. It is not absorbed by any known re-agent and shows no power of chemical combination. The emanation is 100,000 times as active, weight for weight, as radium. Like other gases, it can be collected, confined and handled in ordinary glass containers. This is usually done only when it is mixed with enormously greater volumes of air or other gases. Like other gases, the radium emanation is somewhat soluble in water. It disintegrates at the rate of one-half in about four days, and since the radioactive products into which the emanation disintegrates decay at the rate of one half in a few minutes, it follows that the total radiation from the emanation and the subsequent disintegration products decreases at the same rate as the emanation, namely one half in about four days.

When water with emanation in solution is left in an open bottle the emanation diffuses out, and if the water is shaken up or otherwise disturbed the process of diffusion of the emanation is accelerated. From 10 to 30 per cent of the emanation in solution in water may be lost by pouring from one vessel to another.

The strength of radioactive water is usually expressed in mache units per liter. Radioactive water of 2,700 mache units contains per liter as much emanation as is emitted in thirty days by one microgramme of radium (1 mache unit equals 0.001 electrostatic units, one of which equals 3.33 by 10^{-10} amperes). The radioactivity of water is measured by a fontactoscope, which is an electroscope with a chamber for ionized air and a scale for measuring and timing the discharge. The instrument is standardized by first testing a solution of a known amount of radium chloride which has been sealed thirty days. Great care must be used in sampling the water.

Water is charged either by dissolving the soluble bromide or chloride of radium or by submerging the insoluble sulphate. The later is more economical, but the sulphate must be in a minute state of sub-division and must present the largest possible surface.

There are several ways of accomplishing this:

First—Precipitating the sulphate on asbestos and placing it in a porous cell.

Second—Mixing it with charcoal and forming into slabs.

Third—Mixing it with cement and forming balls.

Fourth—Mixing it with clay and firing it, forming terra cotta.

Most of these processes are protected by patents. The advantage of using an insoluble salt is that it can be employed repeatedly and its use continued indefinitely. The terra cotta rods can be used eighteen hundred years and still have half their radium content available.

Moreover, they avoid introducing into the organism a permanent radio-active body, as is done if a soluble salt is administered.

While a given amount of radium always emits a constant and uniform amount of emanation, the proportion given out by an insoluble salt depends upon its state of subdivision.

In the insoluble salts most of the emanation is occluded by the salt itself; in compact form the sulphate will only yield two and a half per cent, while if it is finely powdered and divided so that it presents a large surface, ten per cent can be obtained.

A uniform strength of emanation is obtained when the same amount of radium sulphate is held in the same state of subdivision, submerged in the same volume of water for the same length of time.

If it is desired to prepare doses of 100 mache units, and the sulphate can be held in such a state that ten per cent of its emanation is available (as is the case when distributed through porous terra cotta) it will be convenient to use an amount of radium which would yield 2,000 mache units and submerge for four days in tightly closed containers, when one half of ten per cent or 100 mache units will be obtained.

The stronger natural springs contain from one to two hundred mache units per liter, with which they are charged while flowing over radioactive minerals or passing through cavities where the emanation has collected. The reason why many mineral waters when drunk at the springs give therapeutic results unattainable when they are bottled and transported, is the speedy dissipation of the fugitive emanation, which is reduced to one half in four days unless there is a source for its renewal. The means of renewing the radioactivity of bottled waters, or of charging any water with emanation, are afforded by the above-mentioned devices, and the physician may prescribe a drinking cure which can be carried out with precision in the patient's home.

The chief effect of the radiations from radium and its disintegration products is to produce an ionization of the atoms of whatever substance the rays penetrate. Chemical effects follow as a secondary result of the ionization. Von Noorden and Falta say that "in contradistinction to all other forms of electro-therapy, we possess in the radioactive substances a means of carrying electrical energy into the depths of the body, and there subjecting the juices, protoplasm and nuclei of the cells to an immediate bombardment by explosions of electrical atoms. We may, therefore, designate this internal treatment with radioactive substances, internal electrotherapy."

How steel darts are dropped from an aeroplane

Insert on the left shows a dart about half size; on the right the box from which they are discharged

Aeroplane Darts and Fire Darts*

Even before the war began the French made many experiments in throwing missiles from aeroplanes. The best known of these projectiles are small bombs or hand grenades about as big as oranges which are launched from tubes or thrown by hand at large terrestrial objects, and which explode on impact. Experiments were made also with a large bomb or shell which was slung beneath the aeroplane and dropped by casting loose its suspending cords. Not many of these large bombs however can be carried by an aeroplane.

A very different missile, the short steel dart, has been frequently used by French aviators during the present war. These darts are rods of pressed steel about as thick as a lead pencil. Four grooves extending through two thirds of the length considerably diminish the sectional area and weight of that part of the dart and give the cross section of the tail the form of a four pointed star.

Hence the dart always falls with its heavy cylindrical and sharply pointed head directed downward. The darts are made in two lengths about four and six inches with corresponding weights of ⅛ and ⅜ ounce. They are thrown with the aid of a special device in bundles containing from thirty to fifty darts but they promptly separate so that they are dispersed over an area of 5 000 square feet on striking the ground when dropped from an elevation of about 1 500 meters or 5 000 feet. This height of fall gives them a striking velocity of 200 meters (about 650 feet) per second, approximately that of a rifle bullet, so that they are able to inflict severe wounds.

The effectiveness of these darts cannot yet be conclusively judged. In a case reported to me by eye witnesses a shower of darts fell upon four companies encamped in a small space. One third of the darts found victims, and inflicted many severe and a few fatal injuries. The conditions were especially favorable for the attacking aviator and this example should serve as a warning not to encamp several companies together. In another case I found that the darts had only slightly wounded a few men. One dart had struck a horse's rump inflicting a painful flesh wound but not disabling the animal.

Another aeroplane missile is the fire dart devised especially for attacking and destroying airships. The experiments with fire darts that have been carried on at the Eiffel Tower and elsewhere in France since 1910 have resulted in the construction of a service type which will probably be employed in the present war. This fire dart is 16 inches long, 3.2 inches thick and 2 pounds in weight. It consists essentially of a tube containing one half pint of benzine and a stout steel needle. In falling it is kept in a vertical position by the action of a little screw propeller at its upper end. When it falls on an airship the point of the needle protruding from the lower end of the tube pierces the gas bag to which the tube is then held fast by six fish hooks. The impact ignites an explosive mixture packed around the needle and the benzine and the gas of the airship are ignited in rapid succession. I have not yet heard of the employment of these fire darts in the present war.

* Translated from the report of a war correspondent of the *Kriegstechnische Zeitschrift*.

† A consideration of the formula $V = \sqrt{2gh}$ and remembering that in the metric system g is about 10 shows that an altitude of about 2 000 meters would be required to produce a velocity of 200 met. sec. even in vacuo. A much greater height would be required to produce the same result in air.—Editor.

Philosophy and Technics*

We regard the triumphal progress of the natural sciences with justifiable pride. An immense fund of knowledge has been accumulated, problems that seemed hopeless have yielded to research, and upon the progressive understanding of the harmony of nature has been reared the imposing edifice of modern technics, the characteristic monument of our era. Although many important questions are still unanswered and extensive fields of knowledge have been only discovered, not explored, yet a sort of stopping point seems to have been reached. The recognition of this fact is manifested in the newly awakened interest in the history of science and in the endeavor to take stock of the results hitherto accomplished and to attain a clear idea of the real value of science.

For the successes of science have not prevented the uplifting of voices warning against over-valuation of those successes. Skeptics have asked if the progress of chemistry and physics has brought us nearer to "the truth." Have we made a single step toward the understanding of the essence of things? The number of these critics is increasing and the expression "bankruptcy of science" is heard. Doubters have arisen in the ranks of science itself. It was a physicist who defined science as "economy of thought," a means of arranging for convenient reference the impressions with which we are stormed by our environment.

Technology appears now to be undergoing a similar development. To a superficial observer it shows splendid triumphs, the accomplishment of results unthought of a few decades ago. In the words of Lamprecht it is "no longer an embryo but a well-developed, beautiful and strong personality in the zenith of its power." This maturity appears to be leading to introspection. We look away from the work in order to discover the true sense of technics, and this inquiry involves others, no less important, for which we have not hitherto had leisure. Whence comes technics and whither does it lead us? Does it mean nothing more than the application of scientific discoveries to the solution of practical problems of utility? Is its sense exhausted in its economic value, in the satisfaction of the impulse toward self preservation, in the chase after wealth and economic power? Or is it based on some idea higher than the principle of utility? In other words, is there a philosophy of technics?

In the year 1877 Ernest Kapp published a book, now almost forgotten, entitled "Outlines of a Philosophy of Technics" (*Grundlinien einer Philosophie der Technik*). The author, who came from the camp of Hegel, endeavored to explain, from the anthropocentric viewpoint, the whole development of technics by "unconscious projection" of the human organism upon external things. In this theory the hand, arm and jaw are the prototypes of the earliest tools and utensils. In the hammer the arm is prolonged and the power of the fist increased, the rigid forefinger with its sharp nail is imitated in the drill, the teeth suggest the file and saw, the hollowed hand is the pattern of the bowl. The parts of the body, especially the hand, project their dimensions and numerical relations also. The span, foot, ell, etc., were the earliest units of measurement, and the ten fingers gave us the decimal system of notation. Even the movements of the limbs are repeated in machines, for levers, pendulums, axles, cords and hinges are found in the human body.

Kapp's theory has been criticised by several writers. Eyth, one of the most philosophical of technicians, has objected that weaving, fire-making and many other important technical arts cannot be explained by the projection of human organs. F. Reuleaux has asserted in his valuable treatise on the theory of machinery that the most rapid progress in technics has been made where men have freed themselves from natural prototypes and tried to solve problems by their own means, often radically different from those of nature.

To these critics it may be replied that imitation does not necessarily mean the production of a perfect likeness. Biology furnishes technics with elements which are employed in altered forms and combinations conditioned by the nature of materials. For example it is not a valid objection to the theory of projection to show that continuous rotation about a fixed axis does not occur in the human body. The movement of the arm in a circular arc about the shoulder joint contains the same element of motion that we find developed and perfected, in the swiftly turning wheel of a machine.

We must, therefore, agree with Kapp that there is a remarkable similarity between mechanical tools and human organs. It is another question whether we shall also agree with him in regarding both as expressions of an unperceived metaphysical principle. Here the philosophy of technics becomes merged in the general problems of philosophy and agreement or disagreement with Kapp will be conditioned by the viewpoint of each individual philosopher.

Metaphysical philosophy is not in great favor nowadays. Philosophy is continually becoming more practical. As natural philosophy it stands in intimate association with the natural sciences, or it seeks a connection with psychology, or it invades the field of ethics. In like manner the philosophy of technics has become a "philosophising about technics," an introduction of psychological, social-ethical and other problems into the field of thought of technics. These questions are discussed by Eberhard Zschimmer in a recently published book (*Die Philosophie der Technik*) which is symptomatic of the changes that have occurred in the meaning and the valuation of technics. Zschimmer sees in technics "the organic part of a greater phenomenon," namely the development of civilization (*Kultur*). By extending the range of our senses and increasing our power over the forces and material of nature, technics assures to the human race the material freedom which it needs for the conscious, creative work of perfecting its development. Hence, the function of the technician is comparable with that of the artist, for each is devoted to the conscious realization of an impersonal idea. As the idea of art is unfolded in the experience and enjoyment of the artist's creation, so the idea of technics is realised in the experience and enjoyment of the material freedom which the work of the technician gives to mankind.

Unhappily we are yet far distant from this ultimate goal of technics. Certain economic dissonances and certain forms of work, specialization and mechanization, are so conspicuous as the results of technical development that the ideal value of technics is difficult to recognize. But technics should not be held accountable for these unwholesome by-products. The object of a philosophy of technics is to prove that technics is something more than an arithmetical problem in national economy and that its true value is unquestionably to be found in the subordination of personal interests to higher ideals.

Instantaneous Photography Without Camera or Plate

An interesting note in the German journal *Prometheus* summarises the account given by Prof Dr P Lindner in *Mikrokosmos* of his experiments in instantaneous photography without camera or plate The negatives were produced on gas light paper by the use of parallel rays and the avoidance of all side lights The source of light was daylight or in photographing constantly moving living objects a direct current arc-lamp, the rays of which were made parallel by means of a concave lens. The objects were placed in narrow shallow glass dishes and the short exposure was obtained by passing a piece of pasteboard with a slit in it before the dishes

Ordinarily photographs without a camera are produced only by means of the Roentgen ray Undeterred by the unusualness of the operation Prof Lindner succeeded in obtaining his shadow like photographs in which the sharpness of the outline is as surprising as the simplicity of the method

Catalysis in the Gas Industry*

When the engineer appeals to the chemist for an explanation of certain reactions and is answered that they arise from 'catalysis he is apt to hint that the reply masks a plea of ignorance. Frequently the suggestion is justified At the same time some catalytic processes are as well understood as the chemist understands any reactions The term catalysis was introduced by Berzelius in 1837 but Kirchhoff Humphry Davy, Faraday and others had quite recognised the peculiar character of the reactions long before that That catalysis plays a great part in the gas industry might not at once be granted but a little reflection will show that catalysis must come in and Dr R Lessing certainly made out a good case for Catalysis in the Gas Industry when recently delivering the William Young Memorial Lecture before the North British Association of Gas Managers at Glasgow

The definition of catalysis for which Dr Lessing expressed preference was that given by Ostwald A catalytic agent is a material which affects the velocity of a chemical reaction without itself appearing in the final products.' The definition Dr Lessing pointed out, implied that the reaction is possible even in the absence of the catalyst, and that the catalyst does not appear in the final product, though it may and does probably form unstable intermediate products which are decomposed and re-formed This view is indeed the basis of one of the hypotheses offered for explaining the phenomena The other hypothesis suggests absorption or occlusion of the reacting substances on the surface and in the pores of the catalyst, the acceleration of the reaction then being due to the higher concentration of the reagents, which may be solid liquid or gaseous. As regards coal and gas, Dr Lessing remarked, there is scarcely a step in the course of the treatment which coal undergoes, from the mine to the burner or chimney flue, on which catalytic influences have not some bearing In 1882 Abel suggested that "coal-dust exerts a contact or catalytic action upon gas mixtures similar to that possessed by platinum ' There is a kernel of truth in that suggestion, though it does not cover the whole range of the phenomena of coal-dust explosions. The occlusion of methane, oxygen and other gases by the large surfaces of the carbon particles would facilitate not only explosive combustion, but also spontaneous combustion. The older view attributed spontaneous combustion and gob-fires chiefly to the presence of pyrites, modern chemistry inclines to the theory that the constitution of the organic matter is often itself sufficient to render spontaneous combustion possible, and that the pyrites act more as catalysts than as the primary cause. Dr. Lessing mentioned in this connection some recent work by K A Hofmann Schlumpelt and Ritter they found that even retort carbon and lamp-black can be oxidised at temperatures below the boilingpoint of water by dilute solutions of potassium chlorate when catalytically activated by osmium trioxide or by solutions of bleaching powder

If coal is subject to catalytic influences at ordinary temperatures at which it appears chemically inert, it stands to reason that these influences will exert them selves strongly at the high temperatures of carbonisation considering the complexity of the organic coal substance which always includes mineral matter All the primary products from coal suffer decomposition on coming in contact with the hot retort walls or hot coke If the walls themselves have such an effect the physical structure and the chemical composition of the retort walls may be expected to have an influence It would be of interest therefore to try glazed and unglazed retorts and retorts made of silica highly aluminous fire-clay and iron These influences will not be great, probably for the retort will generally be covered by deposited carbon yet experiments would be instructive In addition to the ordinary thermal decomposition there are taking place in the retort oxidation dehydration decomposition of heavy hydrocarbons formation of benzine and other ring compounds reduction or hydrogenation—all processes which Dr Lessing suggested from the analogy of cognate reactions the mineral constituents may well affect catalytically These processes do not take place in any fixed sequence of course most of them are reversible and overlapping and it is therefore very difficult to disentangle the threads and to trace the influence of any particular catalyst. But that the influences exist is sufficiently shown by Cooper's coal liming process which has so successfully been revived by R O Paterson of Cheltenham The addition of a minute quantity of lime to the coal does away with stopped ascension pipes and with scurfing troubles that is to say the trouble experienced in removing the deposited carbon from the retort walls Hempel ascribed the peculiar hardness of coke to the formation of silicides like carborundum from the silica and carbon during carbonization Others have proposed to neutralize the activity of a highly siliceous ash by lime Too little is unfortunately still known about the conditions in which mineral matter occurs in coal to speak definitely on such problems the different constituents would interact in the retort but the analysis of the ash does not tell much about the compounds originally present. How it comes about that the coal liming process increases the yield in ammonia and diminishes the formation of organic sulphur compounds was explained in 1902 by the researches of G. T Beilby and G G Henderson They proved that metals like iron copper nickel cobalt take up nitrogen from ammonia at high temperatures forming nitrides which are decomposed again by steam with liberation of ammonia and coals of different ash contents differ indeed in their ammonia yield

Again Dr Lessing continued catalysis is important in water-gas production While coke to which 10 per cent of lime is added gives a gas containing 88 per cent of hydrogen and 12 per cent of methane the addition of 50 per cent of lime will yield a gas with 77 per cent of hydrogen and 23 per cent of methane P Sabatier one of the most conspicuous workers on catalysis of our time found in conjunction with Senderens that both carbon monoxide and carbon dioxide could be hydrogenated into methane by the aid of hydrogen and of finely-divided nickel at a temperature lying between 200 deg and 250 deg Cent. Much hydrogen is however required for this formation of methane—more hydrogen than water gas contains The future of this reaction thus depends upon the cheap generation of hydrogen, itself mostly a catalytic process That the purification from sulphur of coal-gas by iron oxide is essentially catalytic hardly needs emphasis, the iron first yields the sulphuretted hydrogen, and the sulphide is by the air again oxidised so that the iron oxide is restored and sulphur is deposited If this sulphur which blocks up the passages between the oxide particles could be extracted by some solvent, which should not be volatile, the process would be perfect The removal of the organic sulphur and of the carbon bisulphide from the crude gas is or was a still more difficult problem The latter difficulty has quite recently been overcome by the catalysis on a grand scale, of Charles Carpenter in conjunction with Evans and Franks by means of hydrogen in the presence of nickel at 430 deg Cent

We will not follow Dr Lessing in his references to catalysis in relation to by product works and to methodical cracking it would lead us too far into chemistry What we have said will suffice to show how important a part catalysis plays in the coal gas industry Much has been gained by systematic research and a great deal remains to be investigated the field is manifestly one for systematic scientific study

* [illegible]

Coal the Big Item*

The largest single item in the operating costs of any steam power plant is coal In most plants the purchase of coal is a matter of careful consideration and in the larger ones it is usually bought under specifications. Once the coal is in the bunkers this careful consideration stops and the actual burning of the coal is very rarely given more than a passing thought as long as the steam pressure is kept up

The men employed are paid the lowest possible living wage and are chosen more on the basis of the wages they will work for than the results they are able to produce The man who burns the coal can easily vary the efficiency of the boiler by 10 to 15 per cent or the heat absorbed by 15 to 20 per cent yet he is at the bottom of the payroll

No revolutionary advancement has been made in power plants recently and the increased efficiency is accomplished only by taking each process separately and bringing it up to the highest standard It would therefore seem wise in attempting to increase the overall efficiency of a plant to start with the item that represents the largest expenditure and work down the list.

In office-building plants the cost of coal represents some 35 to 40 per cent of the total expenses and boiler room labor 12 to 15 per cent In big plants the cost of coal is 50 to 55 per cent and the boiler room labor 7 to 8 per cent Take a concrete case of a certain office building in New York city that employs two firemen at $800 a year each Their coal costs approximately $10 000 a year If we assume that the boiler efficiency is 60 per cent and that by paying $900 a year men could be obtained who would operate the boilers at an efficiency of 70 per cent, it would be a paying investment. The increase in wages is $000 a year The increase in boiler efficiency amounts to a reduction in coal burned of 14 3 per cent or $1 430 The net result is $830 to the good by the change not a matter of philanthropy

Any plant owner can figure out for himself what a small increase in the boiler efficiency will amount to in dollars and cents and may find it profitable. The efficiency of the boilers may be increased in several ways, but first proper equipment must be furnished Every boiler plant should be equipped with a draft gage stack thermometer and means for determining the CO_2. The cost of this whole equipment need not exceed $100 which would be repaid in a very short time

Then the firemen should be taught the use of this apparatus to determine the proper method of handling the fires to secure the highest efficiency A bonus system for savings over a certain amount would probably be productive of the best results If the firemen are able to save the plant money by their efforts, they should logically be entitled to a part of it.

The Gas from Blast Furnaces—III*

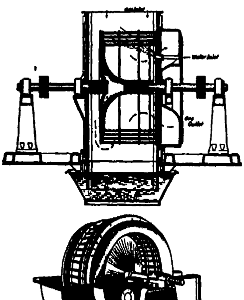
Its Cleaning and Utilization

By J E Johnson, Jr

Continued from Scientific American Supplement No 2041, Page 112 February 13 1915

SCHWARZ-BAYER DISINTEGRATOR GAS WASHER

The Schwarz-Bayer system of gas cleaning makes use of the disintegrator principle and its general arrangement is simple The complete set of gas-cleaning apparatus consists of a disintegrator in connection with a saturating chamber in the form of a hood then a fan placed immediately behind the disintegrator and finally a water separator In case both primary and final cleaning are desired two such sets of apparatus are used the second of which further cleans the gas which has been primarily cleaned in the first



Figs 19 and 20 —Schwarz Bayer disintegrator gas washer

The disintegrator as shown in Figs 19 and 20 consists substantially of two sets of steel pins cold riveted to two steel disks which disks are set side by side and revolve in opposite directions The pins of one revolving disk which interlace with the pins of the other revolving disk form with the water through the effect of rotation and dripping a fine spray or mist which allows a thorough mixture of the water with the gas traveling among and between the pins before leaving the apparatus

The gases from the blast furnace pass from the raw gas mains directly into the disintegrators without previously passing through Zschocke towers or similar preliminary washer or cooler The gas enters through the top of the hood and passes toward the center of the disintegrator while water is being introduced through the sides to the center The hood acts to some extent as a pre-cleaner and cooler as some of the spray from the disintegrators is thrown into the hood and there comes in contact with the hot gas and rapidly evaporates simultaneously cooling the gas By the revolution of the disintegrator the water is projected toward the periphery of the apparatus and is broken up into a fine spray the gas mixes thoroughly with this water and is cooled and most of the dust contained in the gas is precipitated The gases pass through the disintegrator in a current counter to that of the water

The application of the counter-current principle enables the gas to encounter cleaner and colder water in its passage through the disintegrator hence it is better cleaned and its temperature is reduced more nearly to the temperature of the entering cooling water This principle has the effect of materially reducing the amount of water and power consumed Each disk is direct driven by an individual motor and the speed is determined by the degree of cleanliness desired in the gas The gas is drawn through the disintegrator by means of a fan located immediately behind the disintegrator apparatus and passes from the fan to a water separator

The use of pins in this apparatus as a disintegrating medium allows the passage of the gas with very little resistance and a consequent saving in power There is also very little possibility of the dust settling on the pins and clogging up the apparatus

FOWLER & MEDLEY VERTICAL GAS WASHER

This apparatus as shown in Fig 21 consists of a circular cast-iron casing containing a revolving shaft running vertically through the middle On this shaft are fixed a number of disks made either of steel or of cast iron depending upon whether the water used is alkaline or acid Each disk is equipped with a collar separating it from the adjoining disks and each collar is punched or drilled with six holes through which six bolts pass vertically thus holding all the disks in place The shaft is direct driven with a vertical spindle motor Two fixed water sprays are provided for each disk diametrically opposite each other one on each side of the washer and projecting between each pair of disks The jets of water which are introduced through nozzles having about 1/8-inch openings enter with sufficient pressure to strike the collar between the disks and as the disks revolve the water is thrown against the top and bottom of these disks and then against the outside wall of the casing creating a fine spray or mist in the space between the outer edge of the disk and the wall of the casing through which space the gas passes The gas enters the washer at the bottom passes through this spray or mist and leaves clean at the top

This washer can be used for either primary cleaning or final cleaning or both in case final cleaning is desired two washers would be used in series the first apparatus to clean the gas sufficiently for primary purposes and the second apparatus to finish the cleaning of the gas for gas-engine use

FELD GAS WASHER

The Feld washer as shown in Fig 22 consists of a series of superimposed sections, the bottom of each section being provided with ports for the passage of gas The gas enters the bottom of the washer and passes from chamber to chamber to the top whence it is led away Each section or chamber is provided with a series of cones perforated at the top and mounted upon a cast-iron spider, which is carried on a vertical shaft The shaft is suspended at the top in a specially designed anti friction bearing, arranged so as to reduce the power required for operation to a minimum The water is admitted into the top of the washer and overflows from section to section through the gas ports the dirty water saturated with dust leaving the bottom of the washer

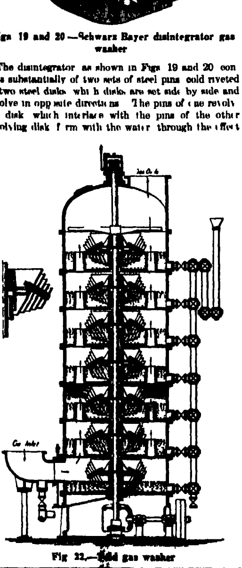


Fig 22.—Feld gas washer

When the shaft revolves the cones do likewise, and the water is raised by centrifugal force along the inner sides of the cones and is atomized at the upper edge This upper edge of each cone is a little higher than the next outer one thereby forming a certain number of horizontal sprays of water, depending on the number of cones The upper portion of the outer cone which is somewhat higher than the inner one is perforated The inner cones supply water to the perforated surface of the outer one This results in the formation of a series of cascades composed of very small drops of water through which the gas must pass en route through the apparatus

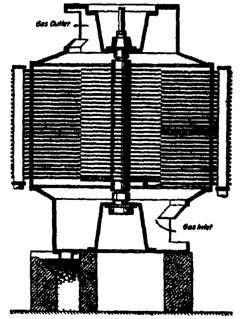

Fig 21 —Fowler and Medley vertical gas washer

The washing is accomplished mostly in the lower sections while the upper sections perform primarily the function of cooling the gas

For primary washing the Feld washer is constructed with seven chambers or sections the lower three being the washing chambers the fourth one being a separating chamber and the upper three being the cooling chambers For final washing in the case of the gas being required for gas-engine purposes the gas after being primarily cleaned is passed through an additional washer of the same general arrangement

KELO CENTRIFUGAL GAS WASHER

This gas washer is constructed by the Roessing-Ernest Company of Pittsburgh Pa and is designed to cool clean and if necessary dry the gas in one apparatus This washer consists substantially of a vertical outer casing a tube whose lower end is provided with serrations extending to within a few inches of a water seal a revolving inverted cup and a sleeve casing at-

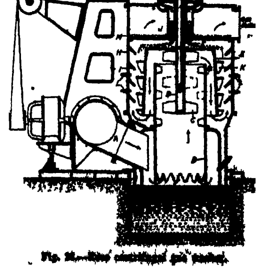

Fig. 23.—Kelo centrifugal gas washer

* Reproduced from Metallurgical and Chemical Engineering

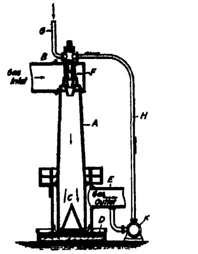

Fig 24.—Sepulchre gas washer

tached to the inverted cup The outer casing the cup the tube, and the sleeve casing are provided with shelves and vanes The apparatus is belt-driven The spindle of the rotor on which the driving pulley is fastened is hollow and the weight of the rotor is taken up by the shaft inside of this sleeve held by a ball bearing which is backed by a rubber buffer in order to equalize any irregularities during rotation

As shown in Fig 23 the hot gas enters the apparatus at the point *A* passes over the water a certain amount of which the gas takes up by evaporation and then passes into the tube *B* through the serrations at its base During its passage through this tube the gas and water vapor are subjected to a thorough beating and mixing by the action of the vanes *C* of the revolving sleeve casing *D* fastened to the top of the inverted cup *E*. The gas passes into this inverted cup which is rotated by the driving sleeve *F* and the pulley *G* and then flows downward, around and under the lower edge of the cup and then upward between the cup and the outer casing *H* The outer surface of the revolving cup is provided with concentric shelves *K* and the outer casing *H* is provided with downwardly inclined shelves *I* which receive the washing water from the water-sealed stuffing box *J* and through a series of water pipes *L* The water, falling on the rapidly rotating shelves of the cup is thrown by centrifugal force against the inner walls of the casing and thence flows downwardly along the inclined shelves, dripping on to the next rotating shelf, and so on In this way the gas, while subjected to a thorough whirling and beating action, has to pass upward through several films of finely divided water or spray while the water passes downward, carrying with it the separated impurities

The apparatus operates on the counter-current principle, the cleanest gas passing from the apparatus meeting the cleanest water entering the apparatus

The upper part of the casing is provided with a rack which, it is stated, can be packed with suitable drying material in case it is desired to dry the gas before leaving the apparatus.

[illegible] GAS WASHER

This washer is designed as a final washer to further clean primarily cleaned and cooled gas to the degree necessary for use in gas engines The principle of this system consists in creating in a vertical tower a very fine spray or mist of water by means of an injector of the Körting type in which water under pressure is atomized by means of compressed blast-furnace gas the spray being produced by the expansion of the compressed gas An intimate mixture of the spray so formed with the dirty gas entering the apparatus is obtained by the arrangement of the apparatus

A separator is provided in connection with this apparatus which consists substantially of a cone arranged in the lower part of the tower in such a way as to leave between the base of the cone and the walls of the tower a very narrow passage through which the gases are forced over the surface of a water seal where the dust and water vapor are deposited

In the accompanying drawing Fig 24 *A* is the vertical tower the lower end of which terminates a short distance above the surface of the water seal *D* Within the lower end of the tower is arranged a conical deflector *C* and near the top of the tower is the gas inlet *B* The lower section of the tower *A* is surrounded by a casing which is open at the bottom and extends beneath the surface of the water in the seal A gas outlet *I* is provided in connection with the outer casing The Korting injector is located at *F* and the feed water for same is supplied through the pipe *G* The pressure is supplied by withdrawing a portion of the purified gas from the outlet pipe *F* and forcing this by the compressor *K* through the pipe *H* into the injector simultaneously with a stream of water

FINAL DRY CLEANING

(Some of these systems can also be applied to primary cleaning)

HALBERGER BETH GAS-CLEANING SYSTEM

The principle of the Halberger Beth system shown in Fig 25 is based primarily on filtering the gas through canvas bags The gas coming from the blast furnace passes through the usual dust catchers and gas mains to a cooling tower where the temperature of the gas is reduced to about 175 deg Fahr The cooling tower is arranged so that the necessary amount of cooling can be accomplished either by air or by direct contact with water depending on the temperature of the gas entering the cooler which temperature is naturally variable in accordance with blast furnace conditions

From the cooler the raw gas by means of the suction of a fan placed beyond the filters or without a fan when the pressure of the gas issuing from the furnace is sufficient passes into and through the canvas filtering bags depositing its impurities on the surface of the bags These canvas filters are contained in a series of double compartments each usually holding twelve canvas bags in rows of three to four Each bag is about 8 inches in diameter by 9 feet 9 inches long and is equipped with a ring at each 18 inches of its length to prevent entire collapse of the bag when cleaning The bags are fastened into a stationary header at the bottom this bottom end being open while the top is closed by a steel plate Each bag is connected with a shaking mechanism located outside and above the filter compartment, and at regular intervals usually about every 4 minutes, these bags are automatically shaken, a compartment at a time for a period of from 15 to 20 seconds By means of a butterfly valve, the uncleaned gas is shut off from the compartment while the shaking is in progress and cleaned gas superheated to the proper temperature of about 175 deg Fahr is forced under pressure into the compartment This causes a partial collapse of the canvas bags which in conjunction with the simultaneous shaking allows the dust to fall from the canvas The separated dust drops into a hopper beneath the sacks whence it is transferred by means of a spiral conveyor to a bin from which it is loaded into cars At the end of the cleaning period the butterfly valve automatically returns to its original position

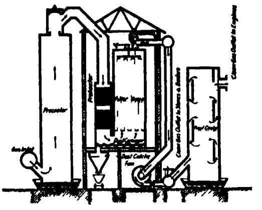

Fig 25—Halberger Beth gas cleaning system

It is quite necessary to keep the temperature of the gas at about 175 deg Fahr as if much higher than this there is danger of scorching the bag while if lower the water vapor in the gas is deposited on the canvas and prevents proper filtration In case the gas becomes cooled below 175 deg Fahr in the cooling tower it is superheated by means of steam or by waste heat from the hot blast stoves to about this temperature before entering the filtering bags After leaving the canvas bags the gas requires no further cleaning for gas engines and is cooled down to the proper temperature in cooling towers of various designs

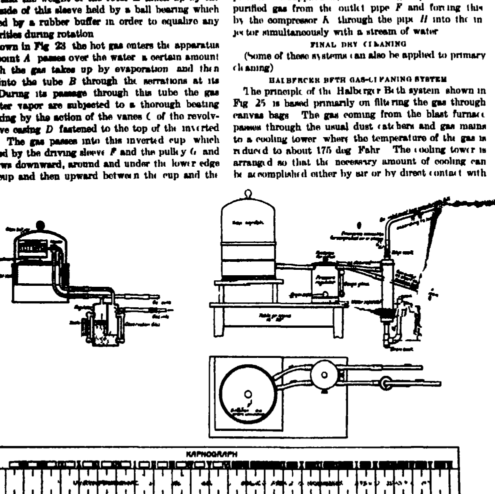
The degree of cleanliness of the gas is indicated by the clearness of the effluent water from these towers and no settling basins are required Consequently this water can be used over and over again which is a material item in districts where water is scarce A further advantage lies in the non-pollution of streams the laws relating to which are very strict in certain districts

This system utilizes the basic principle employed in the bag house system which has been used for the last 20 years in connection with recovering zinc dust from the gas issuing from zinc oxide furnaces and collecting dust from lead smelters

THE KAPNOGRAPH

This instrument shown in Fig 29 continuously indicates the relative degree of cleanliness of the blast-furnace gas going to the gas engines and is extensively used in European gas-engine stations Gas from the cleaned gas main passes through this apparatus and impinges upon a continuous recording chart upon which the dust in the gas is deposited The variations in the amount of dust in the gas are indicated by lighter or darker shades on the recording paper depending on the amount of dust deposited The flow of gas to the instrument is maintained either by the natural pressure of the gas or if this is not sufficient by an aspirator behind the outlet pipe The speed of the gas to the nozzle is kept constant by means of a regulator as shown in sketch the excess gas over the required amount escaping into the outlet pipe by passing under a partition and through a seal of water

(To be continued)



Specimen of strip indicating one days run at a European Gas Engine Plant

Fig. 29—The Kapnograph

A Unique Hydraulic Plant

A novel power plant for supplying electric lighting has been put in operation in Australia The water power is derived from an artesian well from which the water issues under great pressure When shut down this pressure reaches 270 pounds and the working pressure of the jet is 190 pounds This pressure is utilized in two Pelton wheels which drive two dynamos each of 10 kilowatts capacity which supply current to a direct current two wire system comprising eighty 50 candle power metal filament lamps the number of consumers being twenty five and the voltage at consumers terminals 200 volts

Utilizing Old Equipment

An ingenious way to utilize old equipment was recently devised at a power station plant in Kansas Owing to additions made to the plant a larger smokestack was required and when it was completed the old stack which was of steel 8 feet in diameter and 200 feet high was cut down to a height of 35 feet and the lower part reinforced by boiler plate All openings were closed and tightly calked and the old chimney was thus converted into a very efficient water tank at a trifling expense.

NEW BOOKS, ETC

ASSAYING IN THEORY AND PRACTICE By E A Wraight New York Longmans Green & Co 8vo 323 pp illustrated Price $4 net

Laboratory determinations naturally are the ordinary pages of Prof Wraight's useful hand book In the following divisions of the work the author while disavowing any claim to exhaustiveness gives us sound and practical descriptions of dry and wet assaying and of cyanide and mill tests The book issues at the request of his past students of the Royal School of Mines and will prove to them and to other assayers a great aid in the efficient performance of their duties and a detector of the sources of error in their determinations There are plans of laboratories lists of required apparatus tables and conversion factors Prof Wraight desires the work to be considered in the light of an experiment to be followed in the event of success by a second volume dealing with more complicated analysis The wisdom of many living authorities is embodied in the text and in both text and illustration skill and thoroughness are exemplified

LINEN From the Raw Material to the Finished Product By Alfred S Moore New York Sir Isaac Pitman & Sons Ltd 12mo 132 pp illustrated

Uniform with the other volumes of the Common Commodities of Commerce series this monograph attracts our attention with a frontispiece in color showing a field of flax in bloom The Irish linen trade is sketched as it was in the past and as it is to-day The linen manufacturing system in its various aspects is presented in accurate semi popular style and there is a description of the mode of marketing The condition of the operatives is briefly referred to The author has so combined condensation with comprehensiveness that, slim as the volume is it holds a treasury of information

PRINTS A Brief Review of their Technique and History By Emil H Richter New York Houghton Mifflin Company 1914 8vo 188 pp with illustrations Price $3 net

In Prints we are given a charmingly artistic volume that cannot fail to delight any to whom pictures appeal The subject is rich in historic and artistic lore, and its possibilities have been taken full advantage of by the author and the publishers. The work is not intended for the connoisseur who has an elaborate literature at his disposal, so much as for the public who are taking an increasing interest in the broader aspects of the subject As an introduction to the graphic arts it is everything that could be desired It deals with the making of prints the origin of woodcut, the early days of engraving and the activities of Italy Germany the Netherlands France England and the United States Its many illustrations, reproductions toward which great painstaking is manifested are typical of the best and most representative work of the old and the later masters

AN INTRODUCTION TO THE STUDY OF FOSSILS (Plants and Animals) By Hervey Woodburn Shimer A M Ph D New York The Macmillan Company 1914 8vo 450 pp illustrated Price $2 40 net

It is necessary that students bring to the study of paleontology at least such knowledge of biology as will enable them to take up fossils intelligently Prof Shimer's text-book of introductory paleontology has been planned with this need in view It takes up the living forms as types and proceeds to a consideration of their response to environment, thus training the observation to reconstruct the living form from the fossil It gives a comprehensive glimpse of life in the present and of its use in the interpretation of the records of the past Many authorities and institutions have contributed illustration and criticism and the result is a work that may be placed in the hands of the student with confidence in its accuracy and in its adaptation to the requirements of preliminary study

CORK Its Origin and Industrial Uses By Gilbert E Stecher New York D Van Nostrand Company 1914 8vo 83 pp illustrated Price $1 net

Its wide application and its unique characteristics make cork an interesting subject of study Mr Stecher gives us a plain narrative of operations from the corkwood of the forest to the cork of the cellar and the kitchen It may surprise the general reader to learn that so familiar a thing has a name shrouded in mystery Its origin leads us to the romantic shores of the Mediterranean But we have said enough to indicate that this is a very readable monograph which continues its investigations through the botany and chemistry of the substance through the processes of its manufacture on to its many uses and applications

ZOOLOGICAL PHILOSOPHY An Exposition with Regard to the Natural History of Animals By J B Lamarck Translated with an Introduction by Hugh Elliot New York The Macmillan Company 1914 8vo 410 pp Price $4 net

Lamarck's theories and observations still possess something more than historic interest and it pleases us to see so adequate a translation of his great work To such a man as Hugh Elliot we have a right to look for sterling work and a [illegible] summary neither in his translation nor in his masterly introduction has he disappointed us The papers of Lamarck deal with the varied organizations of animals and the faculties derived from them with the physical maintenance of their life and the inclinations to their interesting behavior and to the higher feeling and intelligence noted among the higher orders Lamarck is greatly quoted and little read The latter due doubtless to the obsolete redundant exasperating mode of expression This the translator has carefully corrected without destroying in the least any vital presentment of the work In zoology Lamarck held that all living species being known a linear series would be disclosed each of whose members differed so slightly from their immediate neighbors that the gradations would be almost imperceptible The large gaps which exist he attributes to undiscovered species His translator discloses the errors of his system while frankly acknowledging its ingenuity Lamarck rendered a distinct service to classification and his errors are rather the natural result of the restricted knowledge of his time than to any lack of observation or of perception His zoology physiology and psychology are always most interesting and deserving of the wider appreciation this translation would seem to assure him

THE DAWN OF CHRISTIANITY By Alfred W Martin A M, S T B New York D Appleton & Co 1914 12mo 221 pp Price $1 25 net

A sequel to The Life of Jesus in the Light of the Higher Criticism this series of lectures deals with the formation of the New Testament the influence of Paul and the crystallization of the existing religion into what we now know as Christianity

THE BOOK OF DESTINY And the Art of Reading Therein By Grand Orient Philadelphia David McKay 12mo 280 pp Price, $1

THE OCCULT ARTS By J W Frings Philadelphia David McKay 12mo 286 pp Price $1 net

COSMIC SYMBOLISM Being a Discussion and Exposition of Some Recondite and Obscure Points in the Art of the Kabalists the Mysteries of Sound Form and Number, and the Basic Principles of Cosmic Symbolism By Sepharial Philadelphia David McKay 12mo 296 pp Price $1 25 net

A MANUAL OF OCCULTISM By Sepharial Philadelphia David McKay 12mo 368 pp Price $1 50 net.

Take any golden stiletto that may be lying around prick any number haphazard upon the chart of fortune, and Grand Orient will answer your question through his Book of Destiny Pure rubbish, of course whose only claim upon our leniency must be upon the score of its age In The Occult Arts J W Frings attempts to justify some of them as he could [illegible] it by the conclusions of modern science He abjures the supernatural and he knows how to write In fact he writes so well that the broken link between the occult and the scientific is usually concealed with great skill In the last two books on this occult list we find that Sepharial is a man to be reckoned with, inasmuch as his knowledge of modern research seems to be as broad as his wisdom in astrology and his work is apt to influence minds with a tendency toward mysticism In Cosmic Symbolism we are told that the horoscope of Capt Smith of the Titanic and of W T Stead both point to such a death as overtook them But as to the horoscopes of the vast throng who shared their fate he is silent Some of the horoscopes must have read oppositely—or would he have us believe that Capt Smith and Mr Stead were astrological Jonahs? A Manual of Occultism by the same author is a good exposition of the methods of astrology palmistry and many other pseudo-sciences, and shows a mentality and an application that might have been put to good use in a practical cause.

THE WONDER OF LIFE By J Arthur Thomson M A LL D New York Henry Holt & Co 8vo 658 pp illustrated Price $3 50 net

This is an unconventional introduction to Natural History and Biology taking broad views of the actual lives of living creatures and working inward In spite of the advance of Science Nature's eyes are still full of unfathomable mystery and it is the sense of this mystery which the author would convey and heighten The many colored plates are exquisitely conceived and are mounted upon a dark background that gives an air of distinction to the whole volume. Here are the bird-catching spider the mussel with its precious freightage the death's head moth and the sea-horse threading the branching red coral The text is quite enthralling and no better book could be placed in the hands of young nature students. Huxley's translation of Goethe's aphorisms fitly brings this recital of marvels to a close.

THE GERM-CELL CYCLE IN ANIMALS. By Robert W Hegner Ph D Assistant Professor of Zoology in the University of Michigan. New York The Macmillan Company 1914 8vo. 346 pp illustrated Price $1 75 net.

New and important facts in heredity are being unearthed from time to time and many of these additions to our knowledge are directly due to researches in cellular biology Prof Hegner has taken for his theme the life history of the germ-cell and chiefly of the germ-cell as it appears in animals. Condensation has been imperative so that certain phases have been but lightly touched upon, while those with which the author is most familiar personally are justifiably stressed He has couched his explanations in such language that the reader may derive from them an intelligent satisfaction even though he be unacquainted with the recent progress of cytology The period in the life of the germ-cell which the author has chosen to emphasize—partly because it has been more or less neglected—is that of the segregation of the cells in the developing egg and the visible substances concerned in the process Prof Hegner's original investigations are largely embodied in the text. The germ-plasm theory is expounded in a separate chapter and a long bibliography is appended

STEAM POWER PLANTS A Treatise for Designing and Constructing Engineers Architects and Students By Charles L Hubbard, B S M E New York McGraw Hill Book Company, Inc 1914 8vo 299 pp illustrated Price $2 50 net

HEATING AND VENTILATING PLANTS By Charles L Hubbard B S, M E New York McGraw Hill Book Company Inc 1914 8vo 308 pp illustrated Price $2 50 net

These volumes are Parts I and II of a series on Power Heating and Ventilation of which Part III Isolated Plants and Small Groups is in press Each volume is complete within itself cover design, construction and management and treats the fundamentals of its subject in such a way as to render the work valuable as a text-book for students Part I deals with heat steam fuels and combustion boilers furnaces and chimneys steam engines and turbines with the details of power plant design Part II discusses principles, sets forth the advantages and disadvantages of hot air hot water steam and electric systems of heating and reviews methods for the heating and ventilation of special types of buildings The final chapter is devoted to the care and management of plants The text is interspersed with useful tables and is well and generously illustrated

HANDBOOK OF THE ROCKY MOUNTAINS PARK MUSEUM By Harlan I Smith Ottawa Published by the Department of the Interior Dominion Parks Branch, of Canada

This museum is located at Banff Alberta, and is intended eventually to fully illustrate the natural history of that portion of the Rocky Mountains lying in Alberta and British Columbia and the handbook presents in book form the labels of the museum as already printed and some that are yet to be printed and when finally completed in some future edition will constitute a convenient and popular reference list and description of the chief existent natural history objects of the region

NORTHERN PATAGONIA Character and Resources Vol I Text and maps by the Comisión de Estudios Hidrológicos Bailey Willis Director 1911 1914 New York Scribner Press 8vo 464 pp illustrated Price $6 net

This work is a credit to the Commission under whose auspices it issues It is an admirable description of the Rio Negro-Nahuel Huapi region and of the topographical geologic and economic surveys made by the Commission during 1911 1913 These surveys originated in a national policy of railroad construction which was designed to open up the rich and extensive territories of northern Argentina This is the primary step toward the greatly enlarged prosperity which must follow on the accessibility of such varied resources and speaks volumes for the foresight and practical energy of the administration In our own country where a similar lack of water was encountered geological survey relieved the situation by the discovery of artesian supply and it is our own geologists who secured by Dr Ramos-Mexia must receive recognition for the advantages gained by the field work and the scientific methods used in attacking the problems of Patagonia. The text includes numerous plates of extraordinary beauty and besides the charts of the volume proper thirteen sheets of maps are provided in a separate case which is bound in uniformity with the text.

JAHRBUCH DER WISSENSCHAFTLICHEN GESELLSCHAFT FÜR FLUGTECHNIK II Band 1913-14 Berlin Verlag von Julius Springer 1914 4to 183 pp.

The society which issues this valuable yearbook was founded at Berlin April 3rd, 1912 and its membership includes the leading exponents of scientific aeronautics in all parts of Germany Its honorary president is Prince Henry of Prussia. The meetings of the society are devoted to the consideration of all kinds of scientific and technical questions relating to aeronautics and usually include lectures by specialists, followed by a general discussion. Both the lectures and the discussions are published in the yearbook, each volume of which has appeared in two parts or "Lieferungen." The society has a number of committees on special subjects, such as aerodynamic [illegible], safety devices, medical and psychological questions, aerology electrotechnics, etc., the reports of which are briefly abstracted in the yearbook. In short, this publication is indispensable to the student of aeronautics. The volume under review includes all the lectures delivered before the society during the year 1913 with discussions viz Motor systems by Prof Baumann An Apparatus for investigating wind-structure — the anemocinegraph of the Siemens & Halske Company by Dr H Gerdien Legal questions in aeronautics, by Dr Erythropel The study of the upper air strata through the organization of an international network of pilot-balloon stations by Prof P Polis Aeronautics and mechanics," by Prof A Proll The present state of aeroplane construction, by Prof Reissner What health qualifications should be demanded of the air pilot? by Dr E Koschel The eyes of the aeronaut by Dr Halben The sources of the electrical charge of aircraft, by Dr F Linke; The electrical properties of balloon materials by Dr Dieckmann Hoffentlich (as the Teutonic idiom has it) the present upset in Europe will not permanently check the output of the class of literature of which this yearbook is a typical specimen

SCIENTIFIC AMERICAN SUPPLEMENT

Founded 1876

NEW YORK, SATURDAY FEBRUARY 20 1915

Charles Allen Munn, President
Frederick Converse Beach Secretary
Orson D. Munn, Treasurer
All at 361 Broadway New York

Entered at the Post Office of New York, N Y
As Second Class Matter

The Scientific American Publications

Scientific American Supplement (established 1876) per year	$5.00
Scientific American (est 1845)	3.00
American Homes and Gardens	3 00

The combined subscription rates and rates to foreign countries including Canada, will be furnished upon application

Remit by postal or express money order bank draft or check

Munn & Co., Inc., 361 Broadway, N. Y

The purpose of the Supplement is to publish the more important announcements of distinguished technologists, to digest significant articles that appear in European publications and altogether to reflect the most advanced thought in science and industry throughout the world.

THE APPIAN WAY, NEAR ROME. A GREAT ROMAN TECHNICAL ACHIEVEMENT.—[See page 130.]

Roman Technics and Industry in Early Germany

A Commercial and Technical as well as a Political Conquest

It has been said that it was not love of conquest but economic necessity that led Rome to advance against the Germanic tribes which were constantly pushing southward. As these tribes were subdued Roman sway extended first to the line of the Rhine and the Main, and finally to the shores of the North Sea. The Romans owed the victory, it is claimed, to their superiority in the manufacture of weapons and tools and to their skill in the building of military roads, bridges, and fortifications. After the Germans had learned these arts, according to this theory, they were able not only to drive the Romans out of the conquered provinces, but soon to appear as masters on the other side of the Alps.

Cicero called the Alps a natural wall of defense against the barbarians, and when the campaigns against the Germanic tribes began the Roman legions found these mountain chains a troublesome obstacle. Hence, the Romans were driven to the building of roads over the mountains. The Roman roads, all of which started from the capital, have been divided into roads extending to Africa, Asia, the Iberian Peninsula, the Balkan Peninsula, and by way of Milan to Germany, Gaul, and Britain. In the era of its highest prosperity the roads of Rome were double the length of the equator. It was one of the principles of Roman road-building that a road connecting two places should be straight, without regard to the necessity which might thereby arise for bridges, the piercing of mountains, or the crossing of swamps. The roads had footpaths on each side, were from over thirteen feet to nearly twenty-three feet wide, and sloped toward the sides. The materials of the particular neighborhood were used as far as possible in their construction. There were nine roads across the Alps in the reign of Augustus. One lead over the Great St. Bernard (8,108 feet high) from Mediolanum (Milan) *via* Argentoratum (Strasburg) to Magontiacum (Mainz), and was only for pack-animals, not wagons. A broad wagon-road went over the Splügen to Bregenz and thence to Vindelicorum (Munich). The Romans seldom made tunnels, one of the few being that between Puteoli and Naples.

According to reports that have come down to us, Cæsar seems to have used acetic acid for loosening the rock in limestone mountains, the statement being "he burned away the rock." Livy's reference to this is explained by von Veltheim, thus: "Great piles of burning wood were set close to the rock and it was sought to direct the draft of air so that the flames played constantly against the rock, and when this was red hot or at least very hot and friable water was poured upon it, so that the sudden cooling might split it more thoroughly."

Some interesting statements respecting Roman methods of constructing roads, buildings, and fortifications in what is now the German Empire were made in a paper read last April before the District Engineering Association of Berg by Prof. Dr. Jakobi of Elberfeld and published in the *Zeitschrift des Vereines deutscher Ingenieure*. Prof. Jakobi said:

"From Mainz, which was a great storehouse for military equipments, fine roads ran to Cologne, Trier, Wiesbaden, and the fortress of Saalburg. The road from Mainz to Cologne was built on a dam 2 meters high, 8 meters broad below and 6 above. Other roads ran from Cologne to the mouth of the Weser. Corduroy or wooden roads were laid across the moors, and the remains of such a road were found by Haarmann, near Osnabrück, and given to the Deutsches Museum at Munich. This wooden road, about three meters broad, was somewhat like a railroad track. It consisted of two parallel longitudinal beams on which the cross blocks of oak rested."

The Romans preferred land travel to journeys by water; in going from Rome to Spain the long land route was chosen rather than the trip by sea. Consequently, the art of building bridges was highly developed. The mortar of lime and sand then ordinarily used could not be employed for the pillars of bridges, as it needed air for hardening. Pozzuolana earth and trass which set under water like cement were, therefore, used by the Romans in bridge work. The foundations still exist near Bingen of a bridge with eight arches built 70 B. C. In house-building, besides quarried stone, brick was largely used; in Germany the bricks were manufactured by the legions and bore the particular legion's stamp. In interesting contrast to the Roman houses are the small stone houses of the Lüneberg Moor which are supposedly of early Germanic origin. In these the floor and ceiling are made of slabs of stone over three feet thick.

The Rhine, Main, and Danube may be called the northern boundary of the Roman Empire. Strong fortifications were erected along this boundary as protection against the Germanic tribes. In front of these fortifications ran a ditch with heavy palisades, and in front of the ditch extended the Limes, a strip of land about 120 feet wide and stripped of timber so that the approach of an enemy could be seen. Through the researches of the German Imperial Limes Commission it is known that this protective clearing extended for 550 kilometers from Hönnigen on the Rhine eastward across the Taunus, reached its most northern point at Hainhaus, crossed the Main at Seligenstadt, and went on to the Danube by way of the Odenwald. There were entrances on the Limes at many spots to permit intercourse with neighbors. These entrance-gates were protected by square towers, generally a story and a half high. Traces of about nine hundred such towers have been found. The fortresses or castles lay about 250 meters behind the Limes, and the remains of some eighty of these fortresses have been discovered, the best known being Saalburg Castle, near Homburg-von-der-Höhe. Saalburg was built A. D. 11 and for nearly three centuries was one of Rome's most important strongholds on the Rhine. In 1868 a thorough investigation of the ruins was ordered and in 1896 the reconstruction of the Saalburg was begun, the plans being based on the remains and historical drawings. Prof. Jakobi describes the castle thus:

"The castle is a rectangle with rounded corners 222 meters long and 147 meters broad. The *Porta decumana*, on the side away from the foe, is 6 meters higher than the *Porta prætoria*, the entrance toward the foe. The encircling wall is about 750 meters long and 5 meters high. The Romans opened two quarries from which they obtained the quartzite blocks for the building. The lime came from Berkersheim-on-the-Nidda. The bricks were from the brickworks of the Twenty-second Legion at Nied-on-the-Main. No remains of the hoisting machinery used have been found, but Vitruvius has described such based on the pulley. The ditches before the *Porta decumana* were crossed by a bridge with a wooden railing. The *Porta decumana* had a tower on both sides, the upper story of the towers being united each with the other by a protected passageway. The 8-meter-wide walk along the wall, which was protected by a breast-high parapet, could be reached from this passageway."

The third of the fortresses toward the friendly side is said to have been called the *Retentura*; next came the *Latera prætoria*, the central portion; then the *Prætentura*, the section on the hostile side. The *Retentura* contained the *Quæstorium*, the business office of the battalion where the soldiers were paid. There were found here no less than one hundred and fifty styli, a great many writing-tablets, papyrus rolls, and ink-stands. The *Horreum* was a storeroom for provisions and held the stores of grain; in a dark part of it were kept the fresh and smoked meat and game. The *Prætorium* is a group of buildings 50 meters long and 40 meters broad through which runs the road connecting the two side-gates. It contains the commander's house, the store-room for equipments, the drill-hall, 442 square meters large, and incloses the *Atrium*, an open court for the officers. In the equipment chamber were found apparatus for war of all kinds, especially helmets and weapons. By the aid of existing remains and traditions some of the war-engines, such as catapults, were reconstructed, which when tested worked successfully.

"North of the *Atrium*," continues Prof. Jakobi, "is the sanctuary (*Sacellum*) of the garrison where the standards were kept. These were venerated by the Roman soldiers with a worship similar to a church service. On both sides of the sanctuary were chambers for the guards which could be heated. The heating apparatus was arranged as follows: The brick floor, which is covered with plaster, rests on stone pillars 0.7 meter high. Outside, protected by a projecting roof, is a sunken fire-hole in which charcoal is burned. The gases which pour out flow along under the flooring, which they slowly warm. They are then carried off by vertical clay pipes. An experimental test of the reconstructed heating apparatus gave excellent results. A reconstructed oven also proved to have been correctly made. As further protection against inclement weather, the rooms of the castle had glass windows. Judging from the remains of glassworks on the Feldberg in the Taunus, the glass used at the castle, where it was also blown, was a green soda-glass."

Much care was given to the supply of water both for the castle and the surrounding civil population. Wells were dug and, besides, water was brought from the neighboring mountain streams through hollowed tree-trunks or lead pipes. The remains of furnaces for baths found at Saalburg correspond to those known at Cologne and Pompeii. They are well constructed for their purpose and permit warm or cold water to be turned into the baths at pleasure. In the eighty wells of the civil settlement surrounding the fortress of Saalburg numerous tokens of a vanished civilization were found, such as hooks, rollers, coins, handles, buckets, and shoes. Among the shoes were sandals of wood and leather, low and high shoes, laced shoes, etc. The shoes were made of leather, tanned in the most various ways, from deerskin, goat, calf, and neat skins. Millstones for grinding grain were also found, some for handmills, some to be driven by draught-animals.

The soldiers belonging to the fortress in their free time worked at trades, but the main industrial activity was naturally in the civil settlement, where, beside Roman mechanics, tradesmen, and tavern keepers, there were also soldiers who had served their time. During the excavations the cellar of a tavern was uncovered and in it was found a large number of coins, drinking vessels, and bottles. The Saalburg Museum contains a collection of tools that have been dug up, as hammers, chisels, planes, knives, compasses, as well as what seem to be surgical instruments. The wrought iron and steel needed for weapons and tools were made directly from the ore.

Germans from the valleys of the Main, Lahn, and Rhine came to the fortress and settlements to barter skins, cattle, and game for tools, clothing, mirrors, enamel ornaments, glassware, etc. This contact with civilization taught them new ideas as to the conditions of life and led them to learn handicrafts for themselves.

Agricultural Fertilizers

With the cutting off of the potash supplies from Germany, whose rich deposits have been relied on by manufacturers of fertilizers throughout the world, people have been busily looking about for other sources for this necessary chemical. One of the first directions in which people have turned is to kelp, which is available in great quantities on our western coast, and several projects are on foot to utilize this apparently inexhaustible supply of raw material. There are, however, other sources from which potash may be obtained, and although no great quantities are to be expected in this direction, still in some localities the use of wood ashes might be considered with advantage.

Older people will remember the little inclosures attached to every farm and to many houses in the smaller towns where wood was used as a fuel, in which all of the wood ashes were carefully preserved. This formed the source of the potash used in soap-making, at the time when many farmers made their own soap; and many people spread the surplus on their land as a fertilizer. The most common custom, however, except in remote communities, was to sell these ashes to itinerant collectors, who traveled through the country in the interest of regular manufacturers of potash, and from these came the greater portion of the potash used in the earlier days of our country. Hardwood ash is much richer in potash salts than softwood ashes, and was the only kind that had a market value, although for direct application to the land any kind of ashes is better than none; and while there are few localities where wood is now used as a fuel in sufficient quantities to make the utilization of the ashes of importance, still this is one of the economies that it is as well not to lose sight of.

Besides wood ashes, those from cotton hulls are worthy of consideration in some places, as they are much richer both in potash and in phosphoric acid than the best wood ashes.

There is hardly a farm in the country where quantities of valuable fertilizing material is not constantly wasted as "trash," which is gotten out of the way in the most convenient way possible. Most of it is burned in some out-of-the-way spot and the ashes left where they lie, whereas the burning could as well have been done on cultivated land and the ashes properly distributed. [illegible]

Biochemical Systems*

And Their Function in the Development of the Organism

By Prof. W. Bechterew, of the Imperial Academy of Petrograd

Until recently the differences between human races and individuals, and the differences between animal species, have been attributed to the influence of external factors, while the internal causes of these variations have been neglected. Yet, the importance of external factors in the process of natural selection, though great, is inferior to that of the internal causes of the variations which make the process possible. The latter are the biochemical processes of nutrition and growth.

In regard to plants this statement requires no elaboration, for it is well known that the forms and colors of leaves are affected by chemicals applied to the roots of plants. The question demands more profound study in the animal kingdom, where the processes of nutrition and growth are more complex.

The general influence of nutriment on development is well known, and numerous researches have established a correlation of the biochemical process with the growth and development of certain organs. Every organ pours its specific secretion into the blood and thus affects the entire organism.

The greatest influence is exerted by the so-called glands of internal secretion, including the thyroid, parathyroid, thymus, pineal, hypophysis, subgastric, adrenal, genital, and other glands. Some of these oppose each other. The secretions of the thyroid, adrenals, and hypophysis increase the formation of leucocytes and the elimination of organic salts, while the subgastric and parathyroid secretions produce the opposite effect.

Certain glands exert a specific action on saline exchanges. Injected extract of hypophysis diminishes elimination of phosphorous by the kidneys and increases its elimination by the bowels. Thyroidine increases elimination of phosphorus and calcium by the bowels, and of magnesium by the kidneys. Removal of the parathyroids is followed by increased elimination of calcium.

The nervous influences of the glands are equally various. In general, the glands that stimulate the central nervous system depress the sympathetic system, and conversely. The subgastric and parathyroids stimulate the central and depress the sympathetic system, while the adrenals, thyroid, and hypophysis act in the opposite way.

The glands exert a regulating influence on themselves and each other, through the sympathetic system which connects them. They also affect the blood vessels and the absolute and relative numbers of the various sorts of leucocytes.

The glands act on each other by means of secreted substances which Starling has named "hormones." As a general, but not invariable rule, each gland thus acts on only one other gland.

The antagonism between different glands is indicated by many clinical observations and results of experiment. The ovaries retard the pulse and the formation of bone, both of which are accelerated by the thyroid.

The ovaries are also antagonistic to the adrenals, hypophysis and bone marrow. Adrenaline and cholin, secreted respectively by the central and peripheral parts of the adrenals, antagonize each other. The correlation between the thyroid and the thymus is very evident. The thyroid acts in concert with the adrenals and in antagonism to the subgastric. Hypertrophy of the thyroid is accompanied by hypertrophy of the central part of the adrenals, and glycosuria is caused by the combined action of the increased secretions of both glands. An injection of adrenalin produces glycosuria in a normal dog, but not in a dog which has fasted three days after ablation of the thyroid, while the removal of the subgastric increases the glycosuria caused by subsequent injection of adrenalin. Similar antagonisms exist between the thyroid and hypophysis, and between the adrenals and liver.

The glands also influence the morphological variations of the entire organism. The removal of the thyroid from young animals produces a state of cretinism, with alteration of the skeleton and retardation of the process of ossification. Lesions of the hypophysis produce the diseases called acromegaly and gigantism. According to researches made in our laboratory, the immediate effect of ablation of the hypophysis is increased elimination of phosphorus and nitrogen. Other researches have shown that the secretions of the hypophysis influence the development of the skeleton, the reproductive functions, and the innervation of the blood vessels, bladder, [illegible]. Excessive secretion during growth leads to gigantism; excessive secretion after maturity causes acromegaly, while insufficient secretion produces excessive deposition of fat and atrophy of the genital glands.

An influence of the pineal gland upon the formation of the genital organs has recently been inferred from the very precocious and exaggerated development of those organs that follows lesions of the gland. The influence of the testicles on growth and the development of secondary sexual characters is well known, and is easily demonstrated by experiment. The effects of castration very early in life include a striking deficiency in hair and other cutaneous appendages, deficiency in fat, alterations in the throat and voice, changes in the color of plumage in birds, etc. These effects can be prevented by injecting an extract of testicles. The influence of the secretions of the liver upon the color of the skin has long been known by clinical observation.

We are compelled, therefore, to admit the existence in the organism of certain biochemical systems consisting of the activities of various glands. The formation of bone and muscle, for example, is promoted by the combined action of the thyroid and hypophysis, while this action is opposed by the ovaries. The development of cutaneous appendages, subcutaneous fat, the mammary glands and the larynx is affected by the genital glands and the thyroid. The coloration of the skin and its appendages is related to the activity of the solar plexus and the liver. Muscular strength is influenced by the genitals and adrenals. The development of the brain is proportional to that of the cortical layer of the adrenals, which secretes cholin. Finally, the formation of the genital organs is related directly to the activity of the hypophysis and, less directly, to that of the pineal gland.

Individual, sexual, and racial differences in man, and differences between animal species, are due chiefly to different combinations of the factors described above. The combination is determined partly by cross-breeding, and partly by external conditions.

The great and long recognized influence of crossing is probably due largely to a combination of glandular elements in the embryo and action during growth.

This view is supported by the fact that heredity presents, not a combination of all the characters of both parents, but a selection, which corresponds with the characteristic functions of certain glands. A striking example is furnished by secondary sexual characters, which are often so distinct that they might easily be taken for attributes of species. Yet they depend essentially on the presence of testicles or of ovaries. Other examples are furnished by gigantism and nanism (dwarfishness) which are sometimes hereditary. These peculiarities are caused respectively by excessive or deficient functional activity of the hypophysis and thyroid. In both cases the head is out of proportion to the body. Giants' heads are usually too small and dwarfs' heads are too large. This fact is very significant, because the occiput is formed from connective tissue and not from cartilage, the development of which is determined by the activity of the glands in question. If gigantism and nanism were caused by more general factors all giants would have large heads and all dwarfs would have small heads.

Throughout the animal kingdom, but especially in birds, the lively and quarrelsome disposition of the male, which is manifestly due to the action of the sexual glands, is associated with peculiarities in the development and color of the plumage or other cutaneous appendages, and both phenomena are exhibited most conspicuously in the breeding season.

These facts prove that the differences between species, races and individuals, including differences in temperament and mental character, are conditioned largely by the influence of glandular secretions.

The activity of the glands, however, is affected by external influences, sunshine, humidity, food, and the general conditions of life. Certain butterflies, long regarded as distinct species, have been found to be spring, summer, and autumn varieties. Many observations prove that animals are altered in size and other peculiarities by changes in climate and other external conditions. That these alterations are caused by the agency of the glands is proved by the prevalence of cretinism, nanism, and goiter in certain districts where the development and activity of the thyroid are affected by external factors which have not yet been identified. These are pathological cases, but they differ only in degree from simple morphological variations. In a mountain district in Siberia malformations of the skeleton are so common that the natives do not regard them as abnormal. The cases that I have examined show a shortening of tubular bones, caused by thyroid insufficiency in the period of growth.

It is more important to know if the glandular changes caused by external factors can be transmitted to posterity, for such transmission would explain the evolution of races and species. Here we encounter the great problem of the inheritance of acquired character, which Darwin admitted and which the neo-Darwinians, headed by Weismann, deny. According to Weismann's germ-plasm theory, the organism neither transmits nor acquires anything more than a predisposition, the so-called acquired characters being merely local or general alterations produced by external factors. Many modern biologists, however, agree with Darwin.

The problem has been discussed most clearly by Yves Delage, who distinguishes three classes of acquired characters: mutilations, which are never transmitted; effects of use or disuse, the transmission of which has been neither proved nor disproved; and effects of conditions of life. The third class includes pathological conditions, such as inflammations and epilepsy, the transmission of which was apparently proved by Brown-Séquard, whose results have been confirmed by some later experimenters and contradicted by others. Delage distinguishes as certainly hereditary all diatheses that affect the reproductive organs and all infections (including tuberculosis) that can be transmitted with the sexual products. The transmissibility of other diseases is difficult to prove, owing to the uncertainty, in many cases, whether they are congenital or have been acquired after birth. In regard to other effects of external conditions Delage himself is in doubt, owing to the discordance of the observations.

Standfuss found that changes in color produced in certain butterflies by temperature were transmitted to their descendants. From some butterflies (Vanessa), which changed color under the influence of a very low temperature (23 deg. Fahr.) he obtained 43 descendants of the first generation which showed the same change in color. Of the eight pairs of these descendants that were mated one produced a single specimen that preserved the acquired coloration and three that deviated from the normal in the direction of that coloration. The progeny of the other seven pairs was normal. Fischer found that changes produced in the color and even in the form of butterflies' wings, by exposing pupae to a temperature of 14 deg. Cent. were reproduced in 10 per cent of their progeny, and Pictet has obtained similar results with alterations produced in butterflies by abnormal diet.

By exposure to abnormal temperatures Kammerer caused the normally viviparous black salamander to lay eggs and the normally oviparous spotted salamander to bear living young, and these changes in habit were transmitted to the progeny. A curious change of instinct, artificially induced in a species of frog, was similarly transmitted.

Weismann explains these results by the influence of external factors on the germ plasm, but, in view of the facts described earlier in this article, I am inclined to regard the direct action of those factors as being exerted on the glandular secretions, which may, in turn, affect the germ plasm. At all events, the transmission of certain acquired characters appears to be settled.

This makes it possible to free the theory of natural selection from its great blemish—the element of chance. It has always been repugnant to meet, in a theory of rigorous causality, the hypothesis of accidental variations which became fixed because they proved useful to the species. What is the origin, the cause, of these variations? It seems insufficient to regard them as results of chance. With the recognition of the part which the glandular system plays in the organism we become aware of an interacting system of physicochemical forces in which nothing is left to chance. The variations of equilibrium of these forces under the influence of external factors determine individual differences quite definitely.

Little is yet known of the nature of this equilibrium, and its variations induced by external conditions. In general we know that abnormal glandular activity causes the prevalence of goiter and nanism in the Swiss, Ural, and Caucasus mountains, and in the marshes of the Volga. A more profound study of the etiology of these maladies, and of cretinism, myxoedema, and Basedow's disease, will ultimately furnish an explanation of the internal causes that regulate the development of organisms.

Oxy-Acetylene Welding

How to Make a Complete Oxy-Acetylene Welding Outfit

By A H Waychoff

THE outfit here described was made complete by the writer who felt the need of an oxy acetylene welding outfit yet was unable to buy one owing to the high prices charged by the manufacturers for these outfits After considerable experimenting and the construction of several devices I finally was able to make this outfit at a very small expense in comparison with what they generally cost

Get a new or second hand 50-gallon range boiler A and plug up the hole in the bottom Then as close to the bottom as possible cut out a hole 3 inches or so B and fit it with a hand hole plate and yoke as shown This is for the purpose of cleaning out the sediment which is formed by the carbide dropping into the water In the hole C which is already in the boiler screw a short nipple an elbow and a short length of ¾ inch pipe and on the end of this pipe place a globe valve with a small funnel soldered on The top of the funnel should come about half way up the boiler This is for the purpose of filling the boiler to the required height with water Next get a piece of 10-inch pipe D for the carbide tank about 12 inches long and with a flange screwed on each end Cut out a hole in the top of the boiler 10 inches in diameter and rivet the carbide tank on as shown in Fig 1 using a lead gasket between the flange and the top of the boiler at E to make a perfectly gas tight joint Make a hopper F of 20 gage galvanized sheet iron which will just fit inside of the carbide tank D the bottom part of the hopper at G being 3 inches in diameter Fasten the hopper to the inside of the tank as shown by means of about four small stove bolts Next get a cover plate H to fit the top flange of the carbide tank D and tap out at one side for a 2-inch plug I for filling the carbide tank with fresh material Drill another hole in the center of the head for the feed rod J to work through

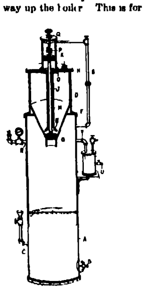

Fig 1—Acetylene generator

An old gasoline engine cylinder K with piston is mounted on the top of the plate H as shown The feed rod J is made of a piece of 5/8-inch steel rod The valve L is a piece of hard wood 1 inch thick and conical shape so as to fit into the bottom of the hopper G when closed Connect the feed rod up as shown one end to the valve L the other to the piston in the cylinder K A galvanized sheet iron tube 1 inch inside diameter M having a flange soldered on at the top at O is fastened to the top plate H by machine screws and at the bottom of the tube a funnel shaped piece N should be soldered on which covers the valve L so the carbide cannot get on the top of it The space between this valve cover N and the walls of the hopper should be about one half inch This allows the carbide to fall through when the valve is open Next tap out for a screw-eye in the top of the piston to which is fastened a closed coil spring P and a hole is drilled and tapped through the cylinder head for a hand screw Q which is fastened to the spring as shown At R mount a gage and safety valve The gage can be an ordinary steam gage registering at least 50 pounds pressure at S fit a half-inch pipe which should be connected up with the cylinder K as shown Next get a piece of 4-inch gas pipe 12 inches long T for the flash back arrester and fit a cover on each end and tap out 6 inches from the top for a small drain cock U Then run a pipe V from the tank through the top plate and down within 1 inch of the bottom of the arrester as shown by the dotted lines Screw in an outlet pipe with an angle valve as shown and a short piece of pipe having grooves cut in it to which the hose to the torch may be clamped on securely

Before operating this generator go all over it to see that all the joints and connections are gas-tight This may be done by putting soapy water on all the joints while there is air or other pressure in the generator If all connections are tight fill the generator with water up to the level of the funnel through pipe C and close the valve Set the safety valve so it will pop at about 30 pounds pressure Then loosen the spring P as much as possible by screwing down the hand screw Q Remove the filling plug I and fill the hopper with one half inch lumps calcium carbide Put the plug back and close the outlet valve on the flashback arrester Gradually tighten the spring P by means of the hand wheel Q which draws up the piston and opens the valve allowing some carbide to fall into the water This generates the

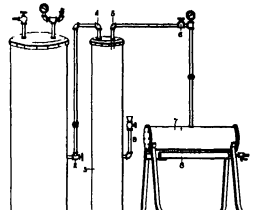

Fig 2—Oxygen generator

acetylene gas the pressure of which acting through the pipe S forces the piston K down and closes the valve L By a few experiments the spring can be adjusted to the proper tension so that the pressure on the piston will automatically close the valve as soon as 7 pounds pressure is reached in the generator Seven pounds is about the best working pressure for all around purposes but for higher or lower pressures a slight turn of the hand wheel will give anything desired The flashback arrestor should be kept full of water up to the drain cock

The oxygen generator shown in Fig 2 is a simple and easily made apparatus and needs very little description Get a 50-gallon range boiler plug up the bottom hole and mount a pressure gage and safety valve on one of the holes at the top as shown In the other hole fit a piece of half-inch pipe with an angle valve also a short piece of half inch pipe with grooves for attaching the hose that conveys the oxygen gas to the torch At the hole in the side of the boiler put a nipple and angle valve 2

Get a smaller tank—the 30-gallon size—3 being about right and pipe up to the large tank as shown at 4 A piece of pipe ½-inch 5 is run down inside tank 3 to within 4 inches of the bottom as shown by the dotted lines

To make the retort 7 get a piece of iron pipe 5 inches in diameter and 18 inches long with a flange and head for each end Mount this on suitable legs and fit a gas or gasoline burner 8 below as shown If copper pipe can be had for making the retort it is much better, but iron is very satisfactory The small tank 3, commonly known as the scrubber should have a filling pipe 9 so that it can be filled with water within 18 inches of the top The retort 7 and scrubber 3 are connected up as shown, a valve any gage being fitted at 6, which should now be tested out carefully for leaks at all joints before putting into operation

To use this generator make a half round tray of thin sheet iron that will just fit inside of the retort, and fill it with a mixture composed of one part manganese dioxide and three parts potassium chlorate Put the tray inside of the retort and bolt the end plates in place and light the burner See that the scrubber 3 is filled with water

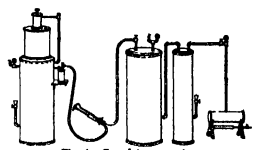

Fig 4—Complete apparatus

and that the valves 2 and 6 are open Leave the fire burning pretty strong until about 30 pounds pressure is obtained then the fire may be adjusted so as to generate the oxygen as fast as it is used From 15 to 30 pounds is about the best working pressure according to the kind of work

When the chemicals in the retort are about exhausted a good way to tell if the retort needs a new charge is to close for a few seconds valve 6 If the pressure rises on the pressure gage at 6 gas is still being formed and more chemicals are not needed If a sheet iron hood be made to fit over the retort to conform the heat, it is better

Care should be taken with the potassium chlorate to keep it in a metal container so nothing can get mixed with it as an explosive compound might easily be formed

The complete torch or blowpipe is shown in Fig 3 For the head of the torch get a 1/8-inch angle valve, 9, and remove the hand wheel and packing nut Take out the valve stem and drill a 1/32-inch hole through it lengthwise as shown in Fig 3 10, also at 11 drill two holes the same size crosswise intersecting the hole 10 This makes four holes or inlets at right angles to the hole 10 Next saw off the valve stem as shown at 12 and screw it into the valve so it comes tight on its seat Then make several tips like 13 Fig 3 having holes from the size of a needle to 1/32-inch in diameter These should have threads cut on them to fit the threads on the inside of the valve bonnet, and are interchangeable for light or heavy work Next screw a piece of 1/8-inch pipe 14 Fig 3 8 inches long into the head as shown. Then get a piece of 3/4-inch pipe 6 inches long with a malleable cap on each end 15 and drill and tap these caps for 1/8-inch pipe Fill the pipe 15 with mineral wool packing it tightly This pipe serves as a handle also as a flashback arrester preventing any flame from getting into the supply hose Screw this pipe or handle 15 onto 14 as shown and on its other end fit a lever gas cock 16 and a piece of pipe about 4 inches long 17 grooved to clamp the hose to.

Another piece of pipe, 18, 1/8-inch in diameter and 15 inches long is bent at one end in a gooseneck, where it screws into the head 9 the gas cock, 16, and connecting pipe, 18, are fitted at the other end

In operation the oxygen comes into the torch through the gooseneck pipe, 18, at a pressure of two to three times that of the acetylene which comes through the pipe, 14. The oxygen, passing through the hole 10 Fig 3, at a greater velocity than the acetylene sucks the acetylene gas through the four holes, 11, Fig 3, and the two gases mix, forming a combustible mixture at the tip The torch is connected up with the oxygen and acetylene generators as shown in Fig 4 by means of two pieces of high pressure hose, each about 10 feet long Be sure to attach the hose from the acetylene generators to the pipe, 14, Fig 3, and the oxygen to pipe 18 Then turn on the the acetylene gas and light it at the tip allowing it to burn for a few seconds, then gradually turn on the oxygen gas until the flame takes a sort of a bluish green color with a distinct white cone shape flame in the center. If the torch smokes, the amount of acetylene should be reduced.

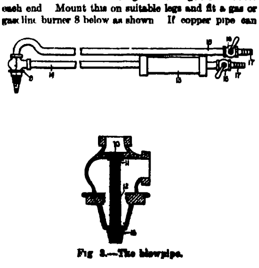

Fig 3—The blowpipe.

Catalepsy in insects

A Physiological Puzzle*

Hypnosis of Animals and Insects and Comparisons With Human Beings

What the magicians did in ancient days before Pharaoh in the way of turning sticks into snakes has often been done since or its converse of turning snake into stick but it remains in great measure a physiological puzzle If the cobra in its threatening attitude be deftly caught behind the head and gently pressed it soon becomes stiff and will remain so for a considerable time, either coiled up or drawn out straight. It has passed into the strange state of animal hypnosis In 1646 the Jesuit father Athanasius Kircher described the famous experiment, de imaginatione gallinæ He laid a hen on the table held it firmly for a little and drew a chalk line in front of its eyes with the result that it remained as if in catalepsy Czermak showed in 1872-1878 that this could be done with many birds, and that the chalk line was quite unnecessary The veteran entomologist Fabre tells us that he and his school companions used to put a whole flock of turkeys to sleep with their heads tucked under their wings Animal hypnosis can also be induced in mammals (guinea pig, rabbit, mouse squirrel, bat, dog cat) and this is usually effected experimentally by fastening them to a board and turning this suddenly upside down Frogs are readily susceptible and newts will also submit.

In backboned animals the state of immobility is scarcely known except in artificial conditions and can scarcely be of much importance in life It is otherwise however when we pass to the analogous death feigning" or catalepsy in certain beetles water bugs, stick insects, and spiders. The immobility occurs in natural conditions and it seems often to save the life The case of the female Galeodes is of special interest since the more than recalcitrant female passes into a convenient hypnosis when she is suddenly seized by the weaker male This may be induced artificially in the sexually mature female by gripping her suddenly in the dorsal region of the abdomen with a pair of fine forceps and raising her from the ground She remains quite passive until she is restored to earth It is very interesting to note that older females, who have paired do not pass into catalepsy, but turn fiercely on the forceps. In the same connection it is worth recalling that when we lift a shore-crab holding the shield between finger and thumb, and wave it in the air it becomes immobile, but the two sexes dispose their limbs in different ways, the female bending them in over the abdomen, as if protecting the eggs. The familiar case of the fresh-water crayfish is interesting because the creature does not pass suddenly into hypnosis, but usually resists for a considerable time It may be fixed in any position of equilibrium—on its head, on its back or even in the normal pose. The stick insect, Dixippus, which feeds at night normally assumes its protective immobile attitude under the stimulus of light, but a mechanical stimulus also serves Schmidt has recently shown that the insect can be fixed in any grotesque attitude for hours on end It has been shown that the transition from one state to the other can in this creature be effected almost in a moment

In a case like the stick insect we cannot but regard the cataleptic habit as of protective value it adds to the safety which the protective form and the protective color also help to secure The creature behaves as if it knew for it almost always disposes itself parallel to the twig to which it is attached Schleip also points out that when it lets go on being touched the elongated straight disposition of the appendages makes it easier for it to slip down among the twigs In Galeodes as we have noted the sudden passivity of the female is of importance in reproduction and a similar phenomenon has been observed in the female octopus In many cases, however it seems quite impossible to maintain that the catalepsy is protective to all Thus Fabre notes that *Scarites buparius* one of the large ground beetles, which a shake sends into a lasting catalepsy is voracious, well armored nocturnal and unpalatable What has it to do with death feigning? Cases of this sort suggest that the cataleptic tendency may be simply a concomitant of a certain type of nervous constitution and that it is only occasionally turned to advantage

According to Mangold the characteristics of human hypnosis are that it is a sleep-like state induced by suggestion that it implies a rapport between the hypnotiser and the patient and an increased amenability to suggestion that it involves an inhibited power of locomotion and of righting the body a change in muscular tonus—from initial increase to somewhat sudden decrease—and a change in sensitiveness which may amount to anæsthesia and analgesia Suggestion is a physically conditioned effect, for which the physiological stimulus seems to be inadequate Little is known in regard to the hypnosis of the highest animals, like dogs and cats the amenability of which to human influence is well known but in ordinary cases it may be concluded, according to Mangold that animal hypnosis differs from man's in the absence of the suggestion the rapport, and the deeper stages It may be induced in animals without a cerebrum which indicates that the psychological factor is unimportant Physiologically considered, however the more typical forms of animal hypnosis must be ranked beside human hypnosis and studied in this light.

The resemblances are many The sleep like state is induced in man by suggestion or psychical inhibition in animals by mechanical inhibition, but in both cases sensory stimuli may assist. These stimuli may be optic (fixing the gaze on some object), or tactile (stroking the skin) or otherwise Sometimes an absence of wonted stimuli may induce the state as in the case of absolute silence The awakening may be brought about by sounds shaking currents of air or electric shocks or it may occur spontaneously There is a great specific and individual diversity in susceptibility the easier the inducing of the hypnosis the deeper and more lasting it is The muscular tonus changes characteristically (now great stiffness and again waxy flexibility) resistance to fatigue is increased Reflexes are to some extent affected by the altered tonus. Sensitiveness to touch and to pain may be greatly lessened and operations may be performed during hypnosis But the senses remain awake and, except in the deeper phases in man, memory partly persists. Anemic symptoms are sometimes observed, but there is no regular alteration in the every day functions such as the beating of the heart or the respiratory movements. Since animal and human hypnoses agree in all these respects Mangold has confidence in his thesis that they are thoroughly analogous phenomena

Finally in his interesting study he proposes a classification

1 Experimental hypnosis induced by psychical inhibition (suggestion hypothesis) (*a*) in man and (*b*) perhaps in some of the highest mammals

2 Experimental hypnosis induced by mechanical inhibition (*c*) in mammals birds reptiles and amphibians and (*d*) in crustaceans and insects

3 Natural hypnosis induced by biological stimuli (*e*) death feigning in crustaceans and insects and (*f*) catalepsy in stick insects

* "Hypnose und Katalepsie bei Tieren im Vergleich zur menschlichen Hypnose." By Ernst Mangold. From *Nature*.

Reinforced Concrete Aqueduct

At Borgone Italy is a good example of an aqueduct or rather flume mounted upon pillar supports the whole being built in reinforced concrete on the Hennebique system The aqueduct runs through open flat country and is about 4 650 feet in length In this way the whole structure is of solid build and is likely to withstand against deterioration longer than the usual kinds Square pillars on both sides uphold the flume part these being spaced at frequent intervals

Glass Surfaced Roads

It is reported that an experiment is being made with a material that heretofore has been a waste product of glass factories for road making This is a thick syrupy liquid that hardens when exposed to the atmosphere forming a substance that somewhat resembles glass. A quantity of this material is said to have been mixed with crushed stone and used to surface a stretch of highway in Illinois, forming a surface that is as smooth as concrete How this surface will stand up under weather and wear will be watched with interest.

Color Photography*

A Brief Review of Its History and Details of Development

By M. C. Rypinski

LIGHT according to the undulatory theory is a sensation produced on the retina of the eye by a wave motion of the ether all light traveling with the same velocity the difference in color sensation being due to differences in wave-length and frequency

Daylight or white light is a combination of color sensations and may be broken up as by a prism or a diffraction grating into its component spectral colors red orange yellow green blue indigo and violet.

Of these color sensations the red has the greatest wave-length and the lowest frequency The wave-length decreases and the frequency correspondingly increases as the violet end of the spectrum is approached

Beyond the red is an invisible portion of the spectrum the infra red and correspondingly beyond the violet there is the invisible ultra-violet both of which are characterized by their chemical action upon light sensitive substances

When rays of light encounter an object they are affected so far as color is concerned in two ways first by reflection second by absorption That is there exists a property in matter which causes a reflection from its boundary surfaces of rays of certain wave-lengths and frequencies and absorption in its mass of rays of certain other wave-lengths and frequencies. All other rays pass uninterruptedly through its mass

An opaque object is one which reflects or absorbs all light falling upon it A transparent or translucent object, on the contrary allows some light to pass through more or less unchanged For example a blue blotter has an opaque blue appearance under ordinary white light because it absorbs mainly red and green and reflects mainly blue transmitting no light In red or green light it would appear quite black A pane of clear window glass transmits all the primaries red, green and blue absorbing practically no light white light therefore entering on one side emerges unchanged on the other Cobalt glass looks blue by transmitted white light because it absorbs red and green leaving the blue to emerge practically unchanged An object due to its particular reflective and absorptive properties may therefore have a very different appearance when viewed by transmitted light as compared with reflected light and its appearance will of course vary with the color of the light source

Another variable is the color sensitiveness of the human eye The normal eye sees all colors but about four per cent of all individuals are color blind and lack the power to distinguish color in certain parts of the spectrum generally the red end In rare cases no color sensation exists at all all objects appearing white or gray in tone[1]

Clerk Maxwell has shown that all color combinations may be reproduced by a mixture of not more than three primary colors red green and blue

Painters and printers are accustomed to regard red yellow and blue as the three primaries but this is due to their working with the subtractive method of color combination where colors are laid one on top of another so that the resultant color in the original or light source color less all of the colors which the various color layers have the property of absorbing

In addition to the subtractive method of color combination there is the additive method by which the final net result is the sum of all the color components used

While most painters use the subtractive method there is a school of painting in which the color is laid on in the form of little dots arranged side by side This additive process gets its color combination from the inability of the eye to distinguish minute objects distinctly at a distance the dots merging and forming a combination image of a color resultant which is the sum of all the colors of adjacent dots

Another characteristic of colored light which plays an important part in color photography is the difference in its action on the retina and its chemical effect upon a photographic plate

It is required of a photographic image that it shall duplicate in proper light relation the object as seen by the eye however the ordinary plate or film emulsion is insensitive to the infra red and yellow portions of the spectrum fairly sensitive to the green, quite sensitive to the blue and highly sensitive to the ultra violet portion An object therefore illuminated by the uninterrupted light of a bright portion of sky (which is largely composed of ultra violet) will show more contrast between lights and shadows in the photographic image than actually exists to the eye. Also the red end of the spectrum (according to the retinal image) appears to be the brightest, while in the photographic image the blue end appears to be the brightest. It is a well known fact that when one wears dark blue or green the studio camera reproduces them as light shades, whereas dark red or yellow appear as dark shades.

In order to correct these difficulties, it is therefore necessary to find some way of making the photographic emulsion first insensitive to ultra violet second less sensitive to violet and blue, third more sensitive to yellow and red.

Considered additively the color yellow is a combination of red and green so that a transparent object which appears yellow by transmitted light is one which absorbs violet and blue and transmits red and green It is obvious therefore that the first two of the above-mentioned requirements may be satisfied if the ultra violet be eliminated and the violet and blue subdued by interposing between the emulsion and object a yellow transparent filter of just the right hue to transmit the amount of blue necessary to effect a balance between its visual and photographic images

The sensitiveness of the emulsion to yellow and red can be increased by utilizing the comparatively recent discovery that certain dyes when mixed with the emulsion render it more sensitive to the yellow portion of the spectrum Others increase the sensitiveness into the red end

Plates or films rendered sensitive to the yellow as well as to the blue and green portions of the spectrum are termed isochromatic or orthochromatic while those which are sensitive throughout the entire spectrum are termed panchromatic.

Curiously enough a panchromatic plate is least sensitive to that portion of the spectrum to which the eye is most sensitive that is, the yellow-green so that unlike ordinary plates which must be developed in a light of low luminosity to the eye (red) a yellow green dark room light of good luminosity may be used

It may be interesting to now briefly review some of the more important steps in the development of our subject The earliest experiments were conducted by Becquerel Seebeck and others commencing about 1810 and were confined to what are termed direct methods of producing photographs in color The indirect methods had not then been thought of By direct methods I mean those in which the light sensitive surface directly takes on the color of the light to which it is exposed The indirect methods contemplate the production of several pictures which are independently colored and then superposed to give the final results

These early experimenters utilized certain light sensitive silver salts which when exposed to colored light took on in a greater or lesser degree the colors falling upon them this appearance, however was not permanent as the colors soon faded In 1868 this phenomenon was explained for the first time by Zenker on the theory of the production of stationary light waves in the silver emulsion by interference of the impinging and reflected light rays.

About the same time it was discovered that many pigment colors were sensitive to light, becoming bleached through its action Wiener in investigating this phenomenon determined that a light sensitive substance can be altered only by those colored rays which the substance absorbs hence red light would have no effect on red but would bleach out blue and green green no effect on green but would bleach out blue and red etc

If therefore a light sensitive surface made up of fugitive dyes of the three primary colors is prepared and exposed under a colored transparency, a color print in duplicate of the transparency will be obtained This theory forms the basis of some of the more important development work now going forward, and it is very probable that it will lead to a satisfactory solution of the problem so far as paper prints are concerned Thus far, however, the "utocolor" paper invented by Dr Smith is the only process based on this phenomenon which is commercially available.

In the course of his experiments Dr. Smith found that certain dyes had a tendency to wander from a coating of one medium to another, as for example, from gelatine to collodion and *vice versa*, due to the affinity which acid dyes exhibit towards gelatine and basic dyes exhibit towards collodion He was able thereby to greatly simplify the selective coloring of his emulsion layers

Utocolor paper involves, however, inherent limitations as to time of printing, brilliance of color, etc., which makes it still somewhat unsatisfactory

In 1891 Prof. Lippman confirmed Zenker's theory, by evolving a direct process producing permanent color transparencies and due entirely to interference phenomena The Lippman process requires an ordinary photographic plate in a special plate holder arranged to hold mercury The plate is placed in the holder with its glass side facing outward and the mercury poured in behind to form a mirror backing for the emulsion. The plate holder is of course so designed as to prevent any leakage of the mercury On exposure in the camera the impinging light rays strike the glass plate first then pass through the emulsion and finally arrive at the mercury mirror surface, being then reflected back through the emulsion retarded in phase angle so that interference with following impinging rays takes place This interference creates stationary light planes of maximum and minimum intensity throughout the emulsion and parallel to the emulsion surface and of course affects the silver in the emulsion in maximum amount at planes of maximum intensity and in minimum amount at planes of minimum intensity After development these planes of reduced silver operate selectively on incident white light so that when viewed along the [illegible] of reflected rays the original picture in its natural colors becomes visible. This process however while capable of very beautiful results, is of scientific interest mainly and very few workers have been able to produce satisfactory plates with it.

It is now in order to mention the work done along lines which form the basis of our successful present-day processes. In 1868 Louis Ducos du Hauron, utilizing the principle laid down by Clerk Maxwell, discovered the "Three-Color Filter Process." This was an indirect additive process and was independently discovered by two other investigators, Charles Cros and Frederick Ives It consisted in taking three consecutive negatives of the colored object to be photographed, each taken through a differently colored filter so as to selectively separate on each of the three negatives a primary color component of the original object. For example one negative would be taken through a red filter which would allow only the red rays from the object to pass through and affect its negative. The second negative would be taken through a green filter, allowing only the green rays to affect its negative. The third negative would be taken through a blue filter, allowing only the blue rays to affect its negative.

Lantern slide positives of these three negatives would then be made and by means of a triple projection lantern the three images from the three slides would be superposed upon each other on the screen, after interposing between each positive and the screen its primary color filters as used in making the corresponding negatives. Each of these three superposed images would have therefore its own primary coloring and they would resolve into a combination image revealing the object in its original colors.

Ives in 1888 showed that the taking filters must collectively transmit all the rays of the spectrum of white light while the viewing or reproducing filters need transmit only narrow bands of the spectrum, representing the three primary colors.

In addition to this additive method of reproducing the original object by means of superposed colored light images, it was shown that the reproduction could be made indirectly and subtractively by superposing prints from the three negatives upon each other. These prints must be very thin and the medium holding the image must be very transparent. They must also be individually dyed to their proper color before superposing. Further, they must not be dyed with a [illegible] the same as that of the [illegible] as in the additive process [illegible] be dyed with the [illegible]

* A lecture given at the eighth annual convention of the Illuminating Engineering Society Cleveland O September 21st 24th 1914

[1] For further data relative to the eye see papers by Dr H H Turner p. 79 and by Dr N M Black, p 426 vol ix, Trans. I E S

For example, the positive printed from the red filter negative is colored with a blue-green (cyan blue) dye, that from the green filter negative with a blue-red (magenta) dye, and that from the blue filter with a red green (yellow) dye.

The reason for this will be evident if we consider that here we are not dealing with overlapping lights, but with overlapping opacities in which each overlapping opacity or print absorbs part of the light transmitted by the other To make this still clearer, consider an actual case, the reproduction say of a blue blotter. One would first take three negatives, red filter, green filter and blue filter The red and green filters absorbing all blue rays would not show any image on their negatives, coming out transparent, while on the blue filter negative would be the well defined image of the blotter, more or less opaque in the high lights and transparent in the shadows

On making positives for the additive or projection process, the red and green filter positives would come out opaque and the blue filter positive would show the image of the blotter transparent in the high lights and more or less opaque in the shadows

On projecting the three positives through their respective reproduction filters, red, green and blue no light would pass through the opaque red and green positives, while the blue positive would project a blue image of the blotter on the screen, brightly blue in the high lights, darkly blue in the shadows thereby producing the desired effect.

With the subtractive process as in the additive process, the positives from the red and green filter negatives would be opaque and from the blue filter negative would show a well defined image transparent in the high lights, more or less opaque in the shadows

On dyeing, the prints from the red and green filter negatives would take up great quantities of their respective cyan blue and magenta dyes The prints from the blue filter negative would take up a small amount of yellow dye in the high lights and more of it in the shadows.

When superposed therefore and examined by ordinary white light the overlapping cyan blue and magenta dyed prints would absorb the red and green but not the blue components of the white light, the light parts of the yellow dyed print would absorb the blue falling upon it only slightly, giving a fairly bright blue reflection for the high lights, while the dark parts would absorb a greater proportion of the blue, giving a dark blue for the shadows thus again giving a correct image of the blotter

This subtractive method forms the basis of all modern color process printing and the commercially available photographic print color processes as follows Sanger-Shepherd, Ives, three-color carbon, three-color ozobrome, raydex, pinatype, polychromide, etc

Next come the single plate color processes, which have contributed largely toward making color photography commercially successful In 1869 Louis Ducos du Hauron conceived the idea of combining the three taking filters of the three-color filter process into a single tri-color filter He constructed the filter by ruling fine lines of the three primary colors, red, green and blue, on a transparent medium, coated on a glass plate, the lines being parallel, adjacent and arranged in the same consecutive alternating order of coloring all over the plate An ordinary photographic plate would be exposed in the camera with its emulsion in contact with the tri-color filter plate, the latter being on the side nearest the lens, so that the light rays would have to pass first through the filter before reaching the emulsion on the photographic plate.

The theory of this process contemplates selective action by each filter line upon the line of light passing through it, with consequent selective action upon the emulsion behind each line Thus the red parts of the image would only affect the emulsion behind the red lines on the filter; the green parts only that behind the green lines and the blue only that behind the blue lines on the filter

After exposure the plate is developed and a positive made in the usual way. The positive and the tri-color filter would then be placed together again, care being taken to align the two so that the image lines on the positive corresponding to the red, green and blue filter lines on the negative were directly in contact with the corresponding red, green and blue lines on the tri-color filter.

On looking through the combined positive and filter, or on projection upon a screen, the picture would appear in its natural colors.

The fineness of the lines on the filter and therefore in the image on the positive, is so regulated as to render them individually indistinguishable, advantage being taken of the limitation of the eye in observing [illegible] objects, as previously pointed out. This not [illegible] the lines together to present a solid image, but also brings about the resultant color combinations of the primary colors necessary to bring out all the various shades of color in the object.

Du Hauron's process was not capable of commercial development, due to the lack at this period of a satisfactory 'panchromatic plate and also due to the mechanical difficulty of ruling up the filter plates

During this same year 1869, Du Hauron conceived the idea of coating the emulsion directly over the tri color filter instead of using a separate plate and after exposure and development chemically reversing the negative to form a positive image In order to overcome the mechanical difficulties involved in a ruled filter he conceived the idea of dyeing minute particles of a transparent substance with the three primary colors, mixing them together intimately and spreading them in a single layer over the glass plate to form the tri-color filter, the emulsion then being coated upon it as previously referred to

It is obvious that this would give a heterogeneous pattern of color instead of a recurring regular pattern as in the ruled line filter It is further obvious that only with a combined emulsion coating and filter as just described can such a filter be used for it would be next to impossible to align such an irregular pattern with its corresponding positive as would be necessary where the panchromatic emulsion was on a separate plate It follows, therefore that a regular geometric arrangement of colors must be used in a tri-color filter or screen (as we will now call it) where the separate single plate process is involved and either a geometric or irregular arrangement may be used with the combined single plate process

Lack of a satisfactory panchromatic emulsion and other difficulties prevented Du Hauron from achieving commercial success with the combined single plate process

During the next forty years various experimenters worked to produce a commercially successful single plate process notably Joly McDonough Lowrie and Miss Warner Their work was all very ingenious and very beautiful results were obtained especially with the Warner Powrie process but commercially they never met with satisfactory development

In 1904 the Lumieres of Lyons France patented the well known autochromo process which represents the successful development of a combined irregular single plate process, along the lines laid down by Du Hauron This process leaves nothing to be desired so far as the production of transparencies quickly easily and with truthful color rendition is concerned It is capable of producing very beautiful lantern slides upon the exercise of somewhat greater care and experience

I will quote from a description of the process by Auguste and Louis Lumiere in a recent issue of *American Photography*

Grains of potato starch are separated by special machinery so as to reject all smaller than 10 or larger than 15 thousandths of a millimeter in diameter (0.0004 in to 0.0006 in) The grains once selected are divided into three lots which are colored orange green and violet by means of appropriate dyes The colored grains are then mixed in such proportions as to give a mixture having no dominant color The extremely intimate and homogeneous mixture of the three colored powders is then coated regularly by means of special machinery on plates of glass previously coated with a sticky varnish After this operation it is necessary to fill the spaces between the grains, which is done by another machine which coats the plates with an extremely fine carbon dust This dust is retained between the grains by the sticky varnish The plate thus prepared is rolled to flatten out the starch grains and produce a three-color mosaic The plate though covered with microscopic elements stained intense orange green and violet seems to present no coloration because the orange, green and violet rays which traverse it combine to form white light.

"How can this mosaic of colored screens give birth to colored images? The mechanism of the genesis of colors is extremely simple It is by subtraction by the partial or total obscuration of such or such a colored grain, that the formation of the most diverse colors can take place. Let us suppose that we obscure the green and the violet grains, the orange grains alone remain, and the plate, viewed with the naked eye, presents an orange coloration If we darken a single color, the hue of the plate is the resultant of light which comes through the other two If the blocking out of a given grain instead of being total, is partial, the resulting color can take the most varied tints

"The sensitive emulsion is coated over the mosaic screen and automatically registers and reproduces the colors of the object Exposure is made through the glass side of the plate so that the light traverses the colored grains and impresses the silver in proportion to the amount of the three primary colors present On treating the plate with a developer metallic silver is deposited over every grain through which light has passed in proportion to the amount of light action Thus, if the object is green every green grain will be covered with silver and if the process were stopped at this stage the image would be red because the image would be formed by the unaltered orange and violet grains This image is the complement of that which it is desired to obtain

But if we dissolve by means of appropriate chemicals the silver reduced by the first development, the green grains would be freed and rendered visible only we should still have the unaltered silver bromide covering the orange and violet grains

Let us proceed then in broad daylight to a second development This unaltered bromide will be affected by light in its turn and blackened by the developer Consequently the orange and violet grains will be masked in their turn and the green grains alone remain visible We have thus reproduced the green image after having passed through a complementary red image

This explanation can be repeated for every other color and one sees that all colors are formed by subtraction by eliminating partly or totally from the range-green violet layer the elements of the colors complementary to the color which is to be obtained This elimination this selection is effected automatically by the colored rays themselves coming from the object photographed

In practice the manipulation of Autochromes is very simple A special yellow-orange screen is placed on the lens The plate in contact with a sheet of black cardboard to prevent scratching of the sensitive coating is loaded into the plate holder with the glass side towards the lens The same developer (metoquinone with ammonia) is employed for both the first and second development Reversal takes place in a bath of potassium permanganate acidified with sulphuric acid and all processes after the flowing of this solution over the plate take place in broad daylight With in 20 minutes of beginning work a finished positive in colors may be produced and as soon as it is dried it may be varnished and bound up like a lantern slide

It should be noted that in this process as in all other single plate processes a compensating yellow or orange filter must be used on the lens to eliminate ultra violet and cut down the violet and blue rays, as previously explained It should also be noted that due to the action of the yellow filter and tri color screen in cutting down the actinic value of the light a great increase of exposure time over the ordinary plate is necessary varying from 25 to 100 times that required for the latter

Following quickly upon the autochrome came the Thames omnicolore and aurora or Dufay dioptichrome single plate processes each representing ingenious attempts to solve the problem in a slightly different way All have achieved fair commercial success but cannot be said to equal that of the autochrome from the standpoint of manipulation or results

In 1913 the Paget single plate process was brought out representing a development of the separate geometric screen method as laid down by Du Hauron It involves a tri-color screen printed in checkerboard pattern upon the screen plate the squares on the checker board being about 1/300 inch on a side A separate taking and viewing screen special panchromatic negative plate special orange filter and special positive plate are necessary Later the company succeeded in combining the viewing screen and the positive into a single plate This process is capable of very beautiful results is especially adapted for lantern slides and threatens to compete seriously in public favor with the autochrome process having an advantage in its possibilities of duplication from the original negative not possessed by the latter

As to the future one may say it is very hopeful The Lumieres and others are diligently working to perfect the bleach-out print process The Eastman Company has recently induced the well known English authority on this subject Dr C E Kenneth Mees to join its staff at Rochester and it is understood that he is actively directing the work along this line It is the hope of all interested in this subject that the near future may have in store for us the perfected photographic print in natural colors

German Plants in Belgium

It appears not to be generally known that many important manufacturing plants in Belgium belonged to Germans and care was taken not to injure these in the bombardments Zinc smelting is going on at Lommel and Overpelt and concerns along the Meuse are in operation

The Spinning of a Web*

A Wonderful Bit of Engineering and Technical Skill

By Frank Cuttriss

A HEAVY thunderstorm in the afternoon having completely destroyed and washed away every trace of the web which a half grown female garden spider had made among the pines on the previous day—night we should perhaps say as we had arrived on the scene at midnight, just as she was completing it—we considered the circumstances favorable for carrying out a project we had long had in mind that of watching the construction of a spider's geometrical web from start to finish

By early evening the storm had passed leaving the earth sodden and the pine foliage sparkling with innumerable raindrops thunder rumbled all around while the clouds were still very heavy and threatening and we were a little doubtful if the weather would permit us to keep our vigil

At seven o clock the spider lay close to the under side of the branch which it had chosen for its home. One could fancy it had foreseen the occurrence of storms for no more perfect shelter could be imagined the branch keeping off direct rain and the foliage around conducting all water away from the spider

At half past seven at eight o clock and half past eight, when we visited it no movement had occurred and it appeared as though our trouble would be unrewarded

We felt certain however that if it were likely to remain fine all night with the prospect of a fine morning the spider would appreciate it and by about midnight construct a new web for the morrow

Nine o clock came and although the clouds were as dense and stormy looking as ever we decided to visit our friend again and see what it was thinking This time we were rewarded for just as we reached the spot it left shelter came out to the tips of the foliage dropped down a line to a point a few inches below ascended to but midway turned head downward and remained suspended for about fifteen minutes (see Fig 2) It then ascended to its nest branch and in a few minutes descended to a branch below Five seconds later it ascended to its original position taking up the line with it so that at 9 25 P M practically nothing visible had been done

Ten minutes later it again emerged descended to a branch below and made fast a line which eventually formed two of the perpendicularly radiating lines. Ostensibly therefore the spider commenced the real business of making its web at 9 35 P M Next from the tips of the foliage of its nest branch it let loose a long line with a free end the object of which soon became apparent for in a few seconds it became attached at an angle of about forty degrees to foliage on the lower left hand Here the instinct—or reason—of the animal especially arrested our attention as at the time the wind was blowing from the right directly in line with the position selected for the web so that in a very few seconds the floating thread streamed out and was caught as described Practically from no other point than that chosen by the spider for setting loose this line could the end in view have been attained

We now conjectured a speedy completion of the structure mentally allowing about an hour for the work We reckoned however without our entertainer for after having done a certain amount of creeping about among the foliage in the vicinity the net result at 9 50 (see Fig 3) was a rough framework two upper and two lower lines radiating from a nebulous sort of ring which was evidently determined upon as the center for the coming web The architect now settled herself comfortably head downward at the junction and took a long rest Twenty minutes elapsed and our spinner appeared suddenly to realise that time was going on and set to work again until at 10 27 P M most of the supports were fixed and nine of the radiating lines were in position (see Fig 4) The spider now ascended to the nest branch and for a considerable time crept about among the foliage At 11 10 P M it descended to the center and remained there head downward for five minutes at 11 15 it was again stirring until at 11 37 the right hand support border line had been fixed as well as twenty two of the radial threads The twenty-seventh radius was fixed at 12 03 A M after which the spider returned to the center and remained head downward (see Fig 5)

In every case where we say rested or remained in center of web or elsewhere we do not wish to convey the idea that the spider did absolutely nothing during the time although for the most part no movement was noticeable.

At 12 30 A M (see Fig 6) the last of the thirty one radial threads was in position the accompanying numbered diagram showing at a glance the order in which they were made (see Fig 1) A short space of time between the placing of all the radii after the twenty seventh was devoted to netting together at the center and fixing roughly concentric threads over larger or smaller segments which the little creature accomplished by traveling to and fro, stopping momentarily to fix the thread as it went the greater part of the central work being done after the fixing of the twenty ninth radial

A few seconds after this the spider commenced one of the most wonderful of the many astonishing features of geometric web-spinning inasmuch as it apparently demonstrates foresight and the possession by the spider of reasoning powers which enable it to use the best means to accomplish the end in view It affixed a thread near the right upper center, then by supporting itself on the radial threads and working towards the left it affixed its thread—always one remove back—in a beautiful volute of about two and three-quarter turns, which was completed at 12 40 A M (see Fig 7)

The objects of this helical line it afterwards became evident, were to keep the radiating threads properly taut and at the intended distances apart also to some extent as a scaffold for the construction of the concentric portion of the web

At 12 41 A M the outermost of the concentric threads was placed by the spider working from the top towards the left and upon arriving at the intended limit on the right it turned about and com

* From Knowledge

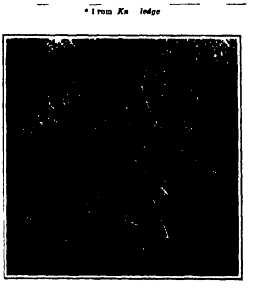

Fig 4—10 30 P M

Fig 5—Midnight

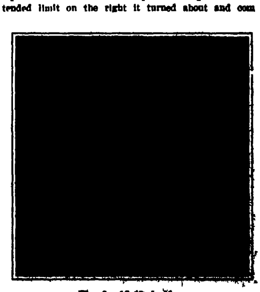

Fig. 6—12:30 A. M.

Fig 7.—12 40 A M

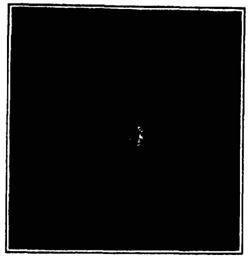

Fig 8—12 50 A M

Fig 9—1 25 A. M

menced the second thread working toward the left by way of the bottom of the web

At 12 43 A M four of these threads had been fixed the spider accomplishing the work by climbing up two threads ahead, descending to just the right distance from the thread last fixed bending its abdomen over the radius next to it, making a decided pause, and with the spinnerets getting the thread which had exuded as it proceeded, fixed at exactly the right spot holding the section just fixed with the hind foot on that side so that it should bear the strain during the operation then up the next radius, and so on over and over again (see Fig 8)

Given a good illumination through the web the most superficial observer would by this time have noticed that a very short time after each division of a concentric was fixed it changed in appearance from the finest streak of reflected light to an apparently stouter and whiter line and would recollect that none of the other lines—supports radii or central netting underwent any such change Upon closer examination and magnification this would be found to be caused by the running together into globules of a viscid matter the result probably of the spider intentionally bringing into action a special secretion We carefully noted the time elapsing between the fixing of a thread and the completion of the studding with viscid globules and found it in every case to be exactly fifty seconds.

The spider now kept on steadily at work the only variation in its movements occurring with the completely circular threads all of which were fixed by the spider working in one direction only (from left to right) instead of turning about as at the end of an incomplete circle and working the next in the opposite direction

Excepting when descending on a line the spider appeared in every case to draw out the thread from its spinnerets by means of its hinder feet used alternately, while the temporary volute or helical thread was cut away apparently by its fore feet as the spider reached it in fixing the permanent concentric lines

At 1 25 A M the finishing touch was given to one of the most perfect webs we have seen (see Fig 9) and the little wonder worker glided up a line connected with the intricate network in the center and took up its position to watch and wait on the underside of the branch the shelter of which it had left nearly four and a half hours earlier

The web constructed by this spider on the previous night—preceding the storm had two stay lines attached one on either side near the center which were affixed to the foliage about four or five inches away

The web we saw constructed had no stay lines the succeeding day being calm and without rain We noted these facts incidentally but would consider it unwise in the absence of recurring confirmatory observations to attribute them to either premonition or coincidence

In connection with the construction of geometrical webs it is interesting to note that, although the foregoing spider on three consecutive days made webs each of which contained the same number (thirty-one) of radii there appears to be nothing to determine the number of these radiating lines that any particular spider will make Perhaps we ought rather to say that the factors determining such are at present beyond our knowledge

An *Aranea umbratica* which we had under observation at the same time as our friend *diademata* constructed—also at midnight—a web twelve inches in diameter This while much larger than that of the garden spider was much more open in structure—a characteristic of this species—and contained twenty two radii only which at the outside of the web were necessarily so much further apart than those of *diademata* as to render it difficult to construct the outermost concentric threads To obviate this difficulty the spider made a temporary helical line of six coils instead of the three which extending much nearer to the outer edge enabled the spider to use it comfortably as a scaffold to get on to the next radius along which it slipped foot after foot precisely in the manner of a tit descending a cord until in position for affixing its thread

Again the web of a *Zilla x-notata* six inches only in diameter had forty radiating threads while a younger spider of the same species constructed a web containing but twenty radiating threads across the mouth of a jug

A vast field for research in this direction is open and although there is evidence of increasing interest in the ways of the much maligned spider it would seem that the fringe only of the subject has been touched and it may well be said of it as of everything else in nature that he who knows most concerning it knows best how little he knows

"Standardizing" the Art of Voice Production

The Fundamental Underlying Principle of Developing the Vocal Muscles

By Floyd S Muckey, M D

The writer considers the establishment of a real standardization of voice production to be the most vital need of the voice-teaching profession The present attempts at standardization however are not only futile but harmful, because they give the musical profession and the student public an entirely false idea of the nature and scope of this problem

All effective singing and speaking involves two things—correct voice production and interpretation. Without correct voice production our speech and song degenerate into mere mummery and disagreeable sounds This effect often becomes distressing or ludicrous to the listener on account of evident bodily strain or facial contortion. With correct voice production the matter of interpretation becomes comparatively simple. The latter depends upon the knowledge and experience of the singer, or in other words upon his mental capacity Since this mental capacity cannot be supplied by the voice teacher, his task can only be to teach the pupil how to secure the correct action of the vocal mechanism. This correct action consists in the free swing of the vocal cords, the free motion of the cartilages of the larynx, and full use of the resonance space We know that this correct action will occur if the voice mechanism is not interfered with, and we also know that incorrect action is due to this interference. There are various forms of interference, each of which leaves its impress upon the quality of the tone. The ear of the teacher may therefore be trained to hear in the quality of the tone the interference with the mechanism. This ability to diagnose interference is the first essential qualification of the voice teacher Correct voice production is involuntary and must necessarily be so while interference is voluntary Any attempt then *to do anything* directly with the mechanism or with the voice itself will inculcate interference and render voice development (development of the vocal muscles) and correct voice production an impossibility A knowledge of the nature of the voice and its mechanism and of the nature of interference must point out the method of its removal The universal tendency of the voice teachers of to-day is to attempt *to do something* with the voice and its mechanism, and hence to develop interference instead of removing it For example, all attempts to "place" the voice to get the tone "forward," to "focus" the tone, or to give it any particular "direction" mean the use of voluntary muscles in voice production. This use means interference which hampers the free action of the vocal muscles, thus weakening instead of strengthening them The result of this wrong teaching is that the voices of to-day (both speaking and singing) are mere caricatures of what they should be Furthermore these voices are at their best for only a few years at most while if they were properly produced they should last until the vocal muscles become palsied by old age More than this the hampering of the voice mechanism by interference takes the mind of the singer away from the sentiment expressed by the words. Nature never intended the singer or speaker to give any thought to the production of his voice. For this reason the voice mechanism was made involuntary, so that the whole mind could be centered upon interpretation Psychology has nothing to do with voice production but is a most important consideration in interpretation

The word *standard* means a measure The thing to be measured in the present instance is the teacher's knowledge This knowledge must be such as will enable him to diagnose and eliminate interference with the voice mechanism and to show the pupil how to develop his vocal muscles What then must the vocal teacher know to enable him to do this? He must know that the voice is a complex sound that each voice tone is composed of several simple tones varying in pitch and intensity These simple tones are called the fundamental tone (the lowest pitch) and the overtones He must know that the elements of voice tones are first pitch second volume third quality Pitch depends upon the rate of vibration of the fundamental tone volume upon the sum of the intensities of the partial tones and quality upon the number and relative intensities of these tones He must know that a wide range of pitch is absolutely dependent upon a free motion of the cartilages of the larynx and that the best volume and quality of tone cannot be secured without an unhampered swing of the vocal cords and full use of resonance It is this correct action of the mechanism which produces a strong fundamental tone—the essential in good volume and quality He must be able to recognize instantly the quality produced by a strong fundamental He must know that the conditions in the throat which produce the strong fundamental tone are such as give an unham

pered action of the vocal muscles and thus preserve the mechanism He must know that resonance is the most important factor in both volume and quality of tone, and that this is caused by the sympathetic vibration of the air in the cavities of the pharynx mouth and nose He must also know that the most rapid development of the voice (vocal muscles) is secured by the daily practices of short soft tones without interference

While there are many other things which the voice teacher should know these are the fundamental factors underlying correct voice production and must form the basis for a standardization of this subject From the foregoing premises the conclusion is inevitable that the diagnosis and removal of interference and a knowledge of how to develop the vocal muscles are the essential qualifications of the singing teacher In the light of these statements let us analyze the recommendations which were adopted by the New York State Music Teachers Association last June This association is one of the oldest and supposedly the one most capable of putting forth a correct standard for the regulation of voice teaching The chairman of the Standardization Committee announced that the following set of recommendations for the standardization of voice teaching was the result of the work of various committees appointed by the association during the past twenty-six years

The Vocal Conference of the N Y S M T A twenty-sixth Annual Convention held on June 18th 1914 unanimously adopted the following recommendations presented by the chairman looking toward the establishment of a standard of musicianship for teachers of singing who desire to become active members of the association

Resolved that before a person is considered qualified to teach singing he should demonstrate to the Examining Committee first that he possesses an ear accurate in the appreciation of differences in the pitch and quality of musical tones and in the pronunciation and enunciation of the English language second that he has sufficient pianistic ability to play simple accompaniments third that he has had at least three years continuous study with some competent teacher fourth that he possesses such elementary knowledge relating to general musicianship as is contained in such a book as Musical Essentials by Maryott fifth that he is familiar with the contents of one or more standard works dealing with Tone Production Voice Development and Interpretation sixth that he possesses the ability to impart his knowledge i e to teach seventh that he has some familiarity with teaching material in the shape of vocal exercises and songs

To show that even the first recommendation in this list is not an essential although it is by far the most pertinent the writer would merely state that Prof Halleck of Columbia University with whom he collaborated in working out the Natural Method of Voice Production was absolutely deficient in what is known as a musical ear He could not tell Yankee Doodle from Old Hundred and yet during the course of this investigation his ear became trained to hear interference just as readily as the writer s With some experience in the removal of interference he would have become a first class voice teacher This shows that while musical ear is a decided advantage to the singing teacher it is not an absolute essential On the other hand there are thousands of persons who possess this musical ear but who are absolute failures as voice teachers for they know nothing about the diagnosis and elimination of interference and the development of the vocal muscles

In considering the second qualification outlined in this standard what is the connection between playing an accompaniment and the diagnosis and elimination of interference? Does the accompaniment played by the teacher take away the interference with the voice mechanism of the pupil? The proposition only needs to be stated to show its absurdity The ability to play an accompaniment is not an essential qualification of the singing teacher

Number three states that the applicant must have had three years continuous study with some competent teacher It becomes necessary at once to define the competent vocal teacher According to our definition the competent vocal teacher is the one who can diagnose and eliminate interference and show the pupil how to attain full development of the vocal muscles and thus make use of all the capabilities of the vocal structures The competent vocal teacher should be able to eliminate all interference at once within a limited range and daily practice for from two to three years without interference should give full development of the vocal muscles with the result that there would be a perfect use of the voice mechanism or perfect tone production

It must be understood that in the beginning a tone produced without interference will be very small but will grow stronger as the vocal muscles develop

There are no singers singing without interference All of them have soft palate interference and on the loud and high tones tongue and false cord interference as well Soft palate interference (raising of the soft palate) takes away more than one-half the resonance space False cord interference prevents the free vibration of the true vocal cords while the tongue muscles interfere with the correct action of the pitch mechanism

This combined interference causes a loss of more than one-half the capabilities of the voice mechanism It greatly reduces the volume limits the range, and destroys the natural quality of the singer s voice

The result is that the voices of our public singers are greatly deficient in these three elements of voice production Such a condition of affairs could not result from competent voice instruction Such instruction covering a period of five years should show some pupils singing their loudest tones without interference. Under these conditions how is the applicant to comply with the third recommendation ?

The fourth recommendation deals with the elementary knowledge of general musicianship While this knowledge is of advantage to a voice teacher or to any one else for that matter even a profound knowledge of this subject would not aid the voice teacher in the diagnosis and elimination of interference and the development of the voice (vocal muscles) This knowledge of general musicianship is not an essential to voice teaching

Familiarity with standard works in Tone Production etc constitutes the fifth recommendation The writer is acquainted with practically all the works written upon the voice and he is in a position to state positively that there has not yet been written a work on tone (voice) production or voice development The various definitions given to the voice prove the truth of this statement. The voice is defined by different writers as vibrated breath "vitalized breath "product of the mind gift from God etc.

A logical discussion based on these definitions would result in a treatise on Meteorology (vibrated breath or air currents) Biology (vitalized breath) Psychology (product of the mind) and Theology (gift from God) This is precisely what we find in these so-called books on voice production. Instead of discussing the voice from its true definition of sound (air-waves) these authors endeavor to describe voice phenomena by a discussion of other sciences. The result is a hodgepodge of the various sciences mentioned. The terms used are necessarily figurative and can give the student no definite idea of the voice or its production. These works can, therefore, afford no assistance in the diagnosis and elimination of interference and the development of the vocal muscles.

A knowledge of the anatomy physiology and physics of voice production is essential to any intelligent discussion or teaching of the voice Since there are no standard works on the voice the student is unable to conform to this "recommendation" The sixth "recommendation" states that the applicant must have the ability to impart his knowledge. The ability to impart knowledge presupposes the possession of such knowledge. Since there are no competent vocal teachers and no standard works on the voice how is the applicant to acquire a knowledge which will enable him to diagnose and eliminate interference and instruct his pupils how to develop the vocal muscles?

In regard to the seventh "recommendation, the teacher might be familiar with all the exercises ever used in voice development, and all the songs ever written and still know absolutely nothing about the diagnosis and removal of interference and the development of the vocal muscles. An exercise is only of value when it is performed without interference, and a song is simply a form of exercise.

This seventh recommendation" requires no knowledge essential to voice development

If anything is ever to be accomplished in voice production there must be a real standardization for the following reasons Every voice is sound, and in every case voice production is sound production The laws which regulate this voice production are precisely the same in every singer and speaker and every mechanism which produces the voice is exactly similar Every vocal mechanism is composed of the same elements—vocal cords muscles and cartilages of the larynx, and resonance cavities The vocal cords are of the same material—yellow elastic tissue—the action of the muscles and cartilages is precisely the same in every individual and the conditions which give full use of the resonance space are identical in every speaker and singer Differences in the size and shape of these various elements account for individual characteristics of voice For these reasons there can be but one standard method of voice production An applicant might comply with all of the recommendations" of the New York State Music Teachers Association and still know nothing at all about the Standard Method of Voice Production

On the other hand an applicant might possess an accurate knowledge of this standard method and still be unable to comply with a single one of the "recommendations

The several state attempts at Standardization are similar in character to that of New York The efforts at Standardization thus far are therefore futile.

The only basis for a real standardization is a knowledge of the anatomy physiology and physics of voice production and its proper application to the voice mechanism This has been carefully worked out by the voice investigation at Columbia University recently completed Any association interested in Standardization need only standardize or measure the knowledge of its applicants by this standard knowledge

An Insoluble Seal for Letters

By "Delta"

A SEAL that will prevent surreptitious opening of letters has long been desired Most envelopes can be only too easily opened by simply steaming one end the letter is then withdrawn read, returned and resealed at one operation But a paper seal can be readily made which will render any letter proof against being opened by steaming the ends as well as the central flap being secured at the time of closing the envelope

The seal is made as follows Use a moderately glazed paper as a base for the seal Prepare a solution of gelatine consisting of 40 grains of gelatine to the ounce of water This should be allowed to soak for half an hour and then may be melted by placing the vessel into boiling water When the gelatine has melted stir the mixture well and then with a flat brush apply the gelatine solution lengthwise on the paper which should have been previously dampened Then hang up the paper to dry When dry coat the paper again brushing the sheet crosswise then dry it once more pinning the sheet at each corner to prevent it from curling When dry lay the sheet face down, and brush the back all over with amyl acetate collodion in a concentrated state then hang it up to dry again Suitable strips may now be cut from the sheet to form the envelope seals. To use these upon the envelope all that is necessary is to dip each one into a solution of common alum for about half a minute made up of 120 grains of alum in four ounces of filtered water or 90 grains of chrome alum. Then place the seal over the flap of the envelope after it has been fastened down in the usual way and, placing a piece of blotting paper upon it, rub it down with the thumb nail until the seal lies flat. It will be found that when the seal has become dry the gelatine has become insoluble It will not be softened by a lengthened period of steaming The coating of amyl acetate collodion makes the seal quite water proof, so that prolonged steaming or even scalding with hot water will not cause the seal to loosen and any attempt to remove the seal will leave a tell tale mark. The paper composing the envelope may soften and the mucilage beyond the gelatine seal liquify but the seal itself will not give way

Concentration and Co-operation in Science*

IN astronomy, for example, the great strides that have been made in the present generation can be attributed to two things first, there is the unprecedented concentration of effort Great telescopes have been erected and great observatories have been built for the purpose of solving single problems or a single group of closely related problems If these problems should remain unsolved in our time the work will be carried forward by a succeeding generation and perhaps completed many years after those who initiated it have passed away Co-operation is another powerful implement that time has placed in the hands of the astronomer, more precious to him than any telescope or any observatory can be. Thanks to it, no pressing problem appears at present above our horizon that is too great for him to attack. If you will examine the working programmes of our astronomical institutions, you will find that much the greater half of what they are doing is being carried out with direct reference to the needs and the activities of other institutions. Co-operation often makes severe demands upon the individual. It means that he must be willing to use his mental and his material equipment in furthering an impersonal plan, it means that he must sometimes subordinate his own judgment to that of others, it means that he must [illegible] that he would like to [illegible] in quite [illegible] than working alone.

*From an address by Prof. Frank Schlesinger, at the meeting of the American Association for the Advancement of Science.

The Chemistry of the Incandescent Gas Mantle*

The Materials Employed and the Steps Taken in its Improvement

By Dr. H. S. Miner

In responding to the invitation to tell you some of the new developments in the chemistry of the incandescent gas mantle, I very much fear that my hearers will be doomed to disappointment if I am expected to describe some startling change that has taken place in that industry. Since the wonderful and spectacular invention of the brilliant Austrian chemist, Dr Karl Auer von Welsbach, who about 30 years ago produced the incandescent gas mantle which in all justice bears his name, the growth of the industry has been marked by steady improvement rather than revolutionary changes, unless indeed we are to include that radical change in the composition of the mantle body which Dr. Auer himself made, when in the early nineties he substituted the thorium-cerium mixture for the more complex lanthanum-zirconium-cerium mantle which had comprised his first commercial mantle body. This was indeed a radical improvement, and it marked the beginning of the general adoption of the incandescent gas mantle.

I have said that the days of *radical* developments seem to be in the past, and yet I never cease to wonder at the phenomenon of the change or petrifaction of the vegetable or organic fiber, reproducing the cellulose fiber in mineral form under the influence of the Bunsen flame and giving the light-producing body with which we are familiar. And although we hear the fragility of the mantle frequently alluded to, yet when I watch its formation in this manner, which seems to be essential to its light-giving efficiency, the strength and resiliency of the mantle is a "nine days' wonder" to me.

The change in the composition of the Welsbach mantle when the mixture of 99 parts of thoria and 1 part of ceria was substituted for the earlier mixture, has ever been to my mind an invention of the highest type, involving as it did the purification of rare earth materials beyond the limits of previous knowledge, and then the development of commercial processes for the production of these rare earths in the highest state of purity.

Notwithstanding the extravagant claims made by many *pseudo* inventors, the thorium-cerium mixture still holds as the essential composition of all Welsbach mantles, and this, and this alone, is the basis of the light-giving qualities of the incandescent gas mantle: although the last quarter of a century has brought us much enlightenment upon the field of rare-earth chemistry, no satisfactory substitute has been found for this early invention of Dr. Auer's. An intimate knowledge of this industry from the very days of its infancy leaves me with an ever-increasing respect for the work of the pioneer, Dr. Auer.

In justice to the faithful and meritorious work of the many rare-earth chemists throughout the world, I would say that their work has resulted in certain changes and improvements in the mantle and burner which have decreased its cost and increased its efficiency and durability. Some of these points I will touch upon.

In the early days a purified cotton fabric was saturated with the thorium-cerium mixture made of materials of as high a state of purity as possible. The purity of the cellulose was found to be absolutely essential, and the well-known bleaching and washing processes were carried beyond the point previously thought to be necessary, and a cotton carrying less mineral substance than the best absorbent cotton was soon produced. Realizing the deleterious influence of foreign substances, such as silica, lime, magnesia, alumina, phosphoric acid, etc., it was recognized that it was just as harmful to have these elements brought to the mantle from the vegetable fiber as from the rare-earth mixture.

It was early recognized that the length of the fiber or staple of the mantle fabric had much to do with its physical strength and its durability. Long staple cottons were used exclusively in the best grade of goods, and the longer fibered ramie or China grass was looked upon with favor when it was first introduced, but it was not used with any success by mantle manufacturers until it had been successfully de-gummed, bleached and washed. The accomplishment of this complex and difficult problem resulted in the adoption of ramie as a mantle fiber, first in Germany and then in other countries. The adoption of ramie fiber made possible the making of the inverted or pendant type, which has since been universally adopted.

Meanwhile, the staple of the fiber had been increased in length from $1\frac{1}{2}$ or $1\frac{3}{4}$ inches to 5 or 6 inches by the substitution of ramie for Sea Island cotton, and that with certain advantages, especially in inverted mantles, yet the ideal had not been reached, and it remained for the artificial silk or artificial cellulose fibers to supply that ideal. The delay in the development of the artificial silk industry caused a delay in the adoption of artificial fibers as a mantle-making body, but its many striking qualities of strength, elasticity and maintained candle-power, have caused a persistence of effort that now had its reward in the arti-fiber mantle.

In the early days, the only digressions from the ideal composition of 99 per cent ThO_2 to 1 per cent CeO_2 were slight variations in these figures within narrow ranges to produce lights with varying degrees of whiteness, an increase or decrease of ceria increasing or decreasing the yellow color of the light produced. The coming of ramie fiber and the inverted type of mantle made the introduction of small percentages of hardening materials essential, and beryllium oxide was found to be an ideal substance for this purpose.

The change of fiber and of the type of the mantles as indicated has caused a complete revolution in the processes of manufacture, and notwithstanding the experience already gained, each one of these changes has called forth a line of research that had made persistent work over a period of years essential before the problem could be considered solved. This is especially true of the arti-fiber mantles, and the changes in manufacturing processes have extended to the collodion or lacquer used to strengthen the mantle for transportation, for the collodion used on the cotton or ramie mantles was found to be entirely unsuited for arti-fiber mantles.

The problem of primary importance for the chemical engineer, as related to this industry, has ever been the manufacture of thorium nitrate, and many changes in the commercial production of this substance have, of course, been effected during the score of years just past. Monazite sand has always been, and still is, the only commercial ore from which thoria could be obtained, and contains from 5 to 6 per cent ThO_2; although small deposits of thorite and thorianite with a thoria content of 50 per cent and 75 per cent respectively have served to keep alive within us an appreciation of, and longing for, a more ideal ore as a source of supply. The high price of monazite—this very low-grade ore from a thoria standpoint, with nearly 95 per cent waste—has thrown upon the thoria content, while still locked up in this phosphate rock, a heavy burden of expense and has made necessary the production of high yields and low costs of operation to keep the cost of thorium salts low enough to make them commercially available.

The first processes used in factory practice were naturally but enlargements of the well-known laboratory methods of analysis, while from this beginning have developed modification after modification, substituting cheaper and cheaper reagents and methods of manipulation until the commercial processes of to-day hardly bear even a "family resemblance" to the first process employed. These modifications are, of course, still continuing, and are made imperative by the fluctuation in price, either of the ore, of some reagent, or of the price of labor. But although there be variations in processes, there must be one unvarying standard ever before the chemist in charge and all of his associates, and that is the absolute purity of the product. Pure thoria is vitally essential, and I am gratified to be able to say for the thoria manufacturers of the world that their product is of very high grade, and is better now, notwithstanding the cheapening and shortening of processes, than it was in the beginning, although even then it was sincerely labeled "C. P."

There are various means, both chemical and physical, of checking and determining the purity of the product, but in the light of experience the most satisfactory method for both accuracy and rapidity is the manufacture of mantles from the thoria as it progresses in purity. The color of the mantle body, the color of the light produced, the presence or absence of shrinkage, the brittleness or flexibility of the mantle, give to the experienced manufacturer a more satisfactory indication of the purity of the product than do the chemical analyses, which are of necessity long and tedious.

The other essential material which must always accompany thoria is ceria, and although it is used in only about one one-hundredth the quantity as thoria, yet its chemistry is just as important and its purity just as essential. I am glad to say that this product is even purer than when Dr. Auer first used it even in larger proportions in his lathanum-zirconium-cerium mantle. The oxide of cerium then obtained was of a reddish-brown tint, while that now manufactured is of a light yellow color, the former product having been slightly contaminated with neodymium, the last traces of which were difficult to remove.

By way of variety, and in order to add zest to the work of the mantle chemist, he has also to manufacture beryllium, zirconium and neodymium, each of which he uses in a limited way, and none of these substances are really easy to produce.

Radio-chemistry has recently thrown the thoria manufacturer into the "lime-light" because of a radio-active product three hundred times stronger than radium, which occurs in and is produced from the thorium which he manufactures. I refer especially to meso-thorium, which a suffering and stricken humanity has implored the thoria manufacturers of the world to save for them, and which these manufacturers are now unitedly conserving as a substitute at least for radium.

With the possible exception of the meso-thorium just referred to, every problem we have mentioned has a bearing upon the characteristics and qualities of some or all types of incandescent gas mantles. There is another and no less important problem, however, that should be alluded to, and that is the protective coating that must be applied to a finished mantle to strengthen it temporarily for transportation. In the early part of 1888 we were dipping the finished mantle in an alcoholic solution of shellac, made slightly flexible upon drying by the addition of a little castor oil. Some essayed to strengthen the mantle by the use of paraffine, and I have in my collection of curios a mantle imbedded in a cake of paraffine, which was to be removed by the melting away of the paraffine wax.

The invention of solutions of nitro-cellulose or soluble cotton opened up a new field of research, and the knowledge gained of the many various forms of nitro-cellulose and the numerous solvents therefor, together with the knowledge and control of such characteristics as viscosity, hydroscopic effects, etc., have made it now possible to prepare collodion solutions of almost ideal qualities for mantle purposes.

And what are these ideals? A collodion must be of the proper viscosity for mantles to be dipped in and withdrawn from it without rupture or strain; it must dry quickly with a film stiff enough for the mantle to be handled with safety, and yet strong and elastic enough to resist handling and shock; it must burn off slowly enough to prevent the mantle from becoming annealed or softened, and yet it must not leave the mantle body sticking to the cap of the burner. A collodion which answers these ideal characteristics is now realized in a nitro-cellulose solution in a mixture of solvents with camphor made flexible chiefly by the use of castor oil.

I said in the beginning that the type of spectacular developments in the incandescent mantle industry were apparently over. At the close of this very general review I am, however, strongly tempted to modify this statement, and to class the commercial development of the arti-fiber or artificial silk mantle in this class of achievements.

The mantle manufacturer has held before himself for a quarter of a century and more certain ideals toward which he has earnestly striven. Some of these have been strength with elasticity, high and maintained candle-power, preservation of color and absence of shrinkage. A realization of these ideals seems finally to have been met in the mantle made from the bundle of elastic, spring-like fibers known as artificial silk, for the strength of these mantles certainly is something phenomenal, the high initial candle-power is not only maintained, but is frequently *increased*. This is made possible by the practical absence of shrinkage upon prolonged burning and by the very curious phenomenon that this mantle does not seem to collect the fine mineral dust from the atmosphere as do those manufactured from the shorter vegetable fibers, cotton and ramie, this siliceous dust having a very great affinity for the basic materials of the mantle body.

The attainment of this ideal has been reached only after years of persistent research guided by many more years of experience in mantle manufacture. Old theories had to be abandoned and former methods completely changed before this mantle was commercially possible. This was a chemical problem of great complexity, and its successful solution arouses such enthusiasm within me that I am tempted to include this among the radical and spectacular developments in our industry.

A clam shell from China with images of Buddha covered with mother-of-pearl.

The Artificial Production of Pearls

By F. E. Chidester, A.M., Ph.D.

The shell of the mussel consists of three layers. The outside horny layer is called the *periostracum;* the middle *prismatic* layer is formed from tiny prisms of calcium carbonate separated by thin layers of the horny conchiolin found in the periostracum; the inner layer is the *nacre* or "mother-of-pearl," which consists of alternate layers of calcium carbonate and conchiolin arranged parallel to the surface. The periostracum and the prismatic layers are secreted from the edge of the mantle, while the nacre is secreted from the whole of the epidermal surface of the mantle. (Parker and Haswell.)

Many centuries ago the Chinese discovered that if foreign substances were placed between the mantle and the shell of a mussel, in many cases a coating of "mother-of-pearl" was laid down. The photograph shown herewith is of a clam now in the Conchological collection of Rutgers College. The wire images of Buddha were placed in the shell, and after a time (probably at least a year) the shell was removed from the water with the images uniformly coated with nacre.

The Japanese have developed the earlier work of the Chinese to a great enterprise under the guidance of the late Prof. Mitsukuri, opening the oysters slightly and inserting bits of sand, images, and particles of limestone, with the result that in many cases pearly excrescences, blisters or "culture pearls" are produced. These blisters are not of any great commercial value and, until recently, attempts to produce free pearls have been notably unsuccessful. A Japanese scientist, Mr. Mikimoto, has produced a few small free pearls by artificial means, but with such difficulty that the enterprise is not commercially profitable. It remained for Dr. F. Alverdes, working in the laboratory of Prof. Korschelt at Marburg, to produce free pearls by mechanical treatment.

Several causes have been suggested for the origin of pearls. Herdman thought that Cestode larvæ were the sole cause of the formation of pearls in the Ceylon pearl-oyster. (Jameson '12a.) Jameson ('02) showed that in the edible mussel, *Mytilus edulis*, pearls are formed as a result of the stimulation of a trematode worm, Gymnophallus. In this case the worm is surrounded by a sac composed of the shell-secreting epidermis, and the sac lays down concentric layers of shell substance and forms a pearl. Jameson opposes the theory of Herdman that the pearls found in the Ceylon oyster are caused by a tapeworm and considers foreign nuclei as exceptional. ('12a.) Rubbell ('11) opposes the parasitic origin of pearls in the fresh-water mussel, finding that they originate around particles of the chitinous periostracum.

Dr. Alverdes distinguished between nucleated and non-nucleated pearls. He calls a nucleus a central body not composed of one of the shell-substances. Frequently the center of a pear is a periostracum center. The nucleus of a pearl may be a parasite, an ovum or a fragment of tissue, or even a bit of quartz. ('13.) Alverdes injected into the connective tissue mantle parenchyma fragments of the shell-secreting epidermis of the mantle, and in other cases a disk of tissue containing both the epidermis and the ciliated lining of the mantle cavity. In both cases the epidermis lived if it found its way into one of the cavities of the parenchyma. (Jameson '14.) It surrounded the cavity with epidermis and formed a closed pearl-sac. Jameson concludes ('14) from the work of Alverdes and others that the real determining factors of pearl production are to be sought in the presence of an island of epidermal tissue in the sub-epidermal tissues, this island having been formed by mechanical processes as in Alverdes's experiments; by a specific parasite, as shown by Jameson in Mytilus; or as Rubbell has shown in the fresh water mussel, from a derangement of the normal mechanism of shell secretion. Alverdes's experiments proved that a nucleus is not necessary for the formation of a pearl.

Industrial Uses of Hydrofluoric Acid*

The larger works on Chemical Technology[1] give the following uses for hydrofluoric acid:[2]

1—Liquid or gaseous hydrogen fluoride is used for etching glass. The liquid leaves a smooth transparent surface, while the gas leaves a rough opaque surface.

2—Hydrofluoric acid in connection with fluorides of the alkalies and some other additions, such as acetic acid or sulphuric acid and others, are used for frosting glass. For this purpose there is in general use a solution of acid ammonium fluoride in hydrofluoric acid. This has the trade name of "White Acid" and contains about 32 per cent NH_4FHF and 20 per cent HF. It works very quickly, e. g., the frosting of electric bulbs requires only about a minute.

3—In the manufacture of spirits from cereals to retard the development of certain bacteria. The yeast is gradually rendered immune to the effects of the acid or its salts, so that the yeast itself is not harmed, but the bacteria which causes the formation of lactic or butyric acid are killed; thus a purer product and a larger yield are obtained. Very small amounts of hydrogen fluoride are sufficient. Effront, who worked out this process, recommends from 5 to 10 grammes hydrogen fluoride per 100 liters of mash. It is not used in the manufacture of whisky, as it is feared that it may have an influence on the flavor. This seems to be well founded, as the flavor of whisky is at least partly due to ethers of the fatty acids.

Ammonium fluoride is, however, used in the fermentation industry to sterilize vessels and rubber hose. But these are always carefully washed with water before they are used again.

4—For the preparation of hydrofluosilicic acid and its salts. (Moissan.)

5—To remove alkalies from the juice of sugar beets. (Thorpe.) This is probably only a proposal and it is not likely that it has ever been carried out on a large scale.

6—To remove silica and silicates from ground anthracite to be used for the manufacture of artificial coal for electrical purposes. This process was carried out for some time on a large scale by F. v. Hardtmuth,[3] but was finally abandoned again as too expensive.

7—To purify crude graphite.

8—For treating earthenware vessels to render them more porous.

The last two uses are mentioned by Prof. Prior[4] in 1903, but I could not find any details in the literature.

9—In dyeing, the antimony acid fluoride[5] is used as a substitute for tartar emetic.

10—To remove substances which have been added to silk to make it appear heavier. (Dammer.)

This process is probably used only in the laboratory in the examination of silk fabrics.

11—In the laboratory, to dissolve and to remove either free or combined silicic acid.

12—To clean sand from cast iron and to remove obstructions from natural gas or oil wells.

I have not learned how much the last named use of hydrofluoric acid is practised.

These last two uses are apparently not practised in Europe. They are mentioned in some of the works on chemical technology, but these all refer to an article published by myself[6] in 1896.

To those uses which have been made known through different publications, the following four, which as far as I know have not been published but are in use in the United States, can be added:

Besides for cleaning cast iron, the acid is also used in large quantities either alone or mixed with sulphuric acid to clean steel pipes to be used to inclose electrical conduit wires. It is also very useful for cleaning brass and similar castings.

The particular advantages over other methods for the same purpose are: 1—This acid dissolves the sand direct, while other acids only loosen it and cause it to drop off by dissolving the metal underneath. Hydrofluoric acid also dissolves the magnetic iron oxide (Fe_3O_4) more readily than sulphuric acid or hydrochloric acid. 2—Hydrofluoric acid leaves a cleaner surface and does not penetrate into the castings as other acids seem to do. If castings which have been cleaned with sulphuric or muriatic acid are well washed and dried and afterward covered with metal or lacquer, it happens quite often that the latter are injured by excrescences starting from the metal.

In cleaning pipes for electrical conduits only the inner side is of importance; it must be perfectly smooth, so as not to injure the covered wires when they are pulled through. On the inside of metal pipes there are patches of melted slag. These can be removed with sulphuric or muriatic acid only by losing considerable metal. This slag, being a silicate, and the magnetic iron oxide, are dissolved directly by the hydrofluoric acid. Frequently a mixture of sulphuric and hydrofluoric acids is used for cleaning such pipe.

Cast steel can rarely be cleaned to advantage with hydrofluoric acid, because the loam used for molds is baked very hard and dissolves very slowly in hydrofluoric acid.

Castings and pipe are cleaned in the following manner: The acid is used in varying strengths, according to the condition of the material to be cleaned and the available time. One part 30 per cent hydrofluoric acid is mixed with 4 to 40 parts of water, which gives a solution containing 6.0 to 0.7 per cent hydrofluoric acid. The weaker acid is preferable if enough vessels are on hand to leave the castings in the acid pickle sufficiently long.

* Presented by K. F. Stahl before the Pittsburgh Section of the American Chemical Society, October 15th, 1914.

[1] Dammer, Molinari, Ed. Thorpe and Henri Moissan.

[2] It is generally known that hydrofluoric acid produces very painful inflammation if allowed to come in contact with the skin. The remedy usually recommended is washing with water and then with dilute ammonia water. This is effective only with weak acids; with stronger acids, particularly the 60 per cent, washing alone, even if done immediately, does not prevent inflammation, but if the washing is continued for about half an hour by holding the affected part under flowing water the bad effects will be prevented or at least materially reduced. Washing must, of course, begin at once after the acid has come in contact with the skin. Very dilute acid, i. e., up to 5 per cent, produces no ill effect by temporary contact with the skin.

[5] Dammer, 1, 871.

[6] Z. angew. Chemie, 1896, p. 266.

It requires about 12 hours to clean castings with 1 per cent acid. Comparatively more acid is required if stronger acid is used, but the time of cleaning is reduced.

Round or square wooden tanks without any protective covering are generally used. For economy in handling small castings they should be placed in a second wooden vessel perforated on the sides and slightly smaller than the first one. This has the advantage that the sand which falls off remains on the floor of the inner vessel, is lifted out with it and is thus removed from further action of the acid.

Heating accelerates the action of the acid bath, which can be used repeatedly if for every fresh batch of castings about 1/3 of the amount of acid originally used is added.

If the castings are to remain bright they should be washed with hot water as soon as they come out of the acid pickle, so that they dry off quickly; otherwise they can be washed with cold water. To the last wash water some milk of lime is usually added to prevent rusting.

Under the published uses of hydrofluoric acid, the one for etching glass was mentioned first; but it is very strange indeed that the use of strong hydrofluoric acid for *polishing cut glass*, which has been in practice for a number of years, is nowhere mentioned. It started about 18 years ago and is at present probably in use in all of the cut glass factories in this country.

The last operation in manufacturing cut glass is the polishing of the surfaces which have previously been cut into the glass. This was formerly done with oxide of iron or oxide of tin. As every plane had to be polished separately by skilled labor it was slow and expensive.

A finer polish is now obtained in the following manner: For vases and similar shapes, where the polish is required only on the outside, a wooden stopper is cemented in water-tight with paraffin or wax. Other surfaces which are not to be touched by the acid are also covered with asphaltum, wax or some similar substance. It is essential that all surfaces to be polished must be absolutely clean, and especially free of every trace of grease. To accomplish this, they are brushed with soda solution by girls who wear rubber gloves, then they are washed in clean water and after most of the water has dripped off they are dipped in the acid bath.

Generally a mixture of 1 part by weight of sulphuric acid, 66 degrees Baumé, with 3 parts 60 per cent hydrofluoric acid is employed. This mixture is in a lead vessel, large enough to submerge the largest pieces to be polished. It is placed directly in front of a ventilating tube, through which a ventilator creates a strong suction. This protects the polisher from the strong vapor given off by the acid mixture and he needs only a rubber apron and long rubber gloves for his protection. The perfectly clean and partly dried off pieces of glassware are held one at a time from ½ to 1 minute in the acid, and then immediately dipped into water.

By the action of the acid on the glass a thin crust is formed consisting of calcium fluoride, probably with some sulphate of lead and sodium or potassium fluoride. This is removed by brushing with water, after which the pieces are washed off in clean water and dipped again in the acid. The polish is usually complete after three dippings. Every piece is carefully inspected and defective spots are polished by hand; if the grinding was carefully done, this is rarely necessary.

Experiments undertaken to polish plate glass in the manner described did not produce satisfactory results. The surface obtained was glossy, but in place of being perfectly smooth, as in the case with cut glass, it was somewhat wavy. This difference may be caused by the materially different composition of the two glasses or by the apparently different manner of their production.

Buildings and monuments, particularly in industrial districts, obtain in course of time a dark color. This can be removed and the original color restored with hydrofluoric acid better and cheaper than in any other way; 15 per cent acid is generally used (30 per cent is diluted with the same volume of water). The workman wears rubber gloves and proceeds as follows: Two or three square feet of the surface are first moistened with a brush or sponge, then painted with the 15 per cent acid (for larger surfaces a whitewash brush can be used). After a minute or two the surface is scrubbed with a stiff brush and rinsed with water. The action on granite or sandstone is negligible; marble is acted on a little more and it is advisable to protect polished surfaces.

The glass roofs of greenhouses are cleaned in a similar manner. During the summer those are usually whitewashed to moderate the rays of the sun. This protective covering, on which also accumulates some dust and soot during the summer, has to be removed in the fall, as during the winter all the sunlight obtainable is needed. This is done by painting the surface of the glass with 15 per cent hydrofluoric acid, using a 6 to 8 inch whitewash brush fastened on a long pole. After a few minutes, when about 8 rows have been painted, the acid is washed off with water. In this manner the glass is made as clear and transparent as new, much better than was formerly possible with muriatic or oxalic acid.

If the houses are old and the panes of glass not absolutely tight, the glass in those houses where ferns, smilax and asparagus are raised should be cleaned before the plants are set out, because they sometimes get yellow spots from the fumes of the acid, which penetrate through the crevices even though the fumes are not perceptible to human beings.

A Perpetual Calendar

To the Editor of the SCIENTIFIC AMERICAN SUPPLEMENT:

I have examined with a good deal of interest the 4,000-year calendar printed in the SUPPLEMENT to the SCIENTIFIC AMERICAN on page 400, December 19th, 1914. I have done a good deal of work on calendars, and I have taken the trouble to study out this rather complex affair and find it is not reliable. I enclose a table of dates which I have looked up in this calendar, with their comparison with the correct dates. In this table there are twelve old-style dates, and Kennedy's calendar gives eleven of them wrong.

The change from old style to new style was made in England and her colonies in September, 1752, the days between September 2nd and 14th being omitted from this month; but there was no change in the succession of the days of the week. September 2nd, 1752, was Wednesday and September 14th in the same year was Thursday, being the following day. Kennedy's calendar gives both of these days as Thursday. Kennedy finds that Columbus discovered America on Monday, while history tells us it was Friday.

I have worked out a calendar very much simpler than this of Kennedy's, which covers the whole Christian era, and am sending you herewith a photographic reproduction of it. If the SCIENTIFIC AMERICAN SUPPLEMENT desires to publish this calendar I shall be glad to have it do so. The explanations given at the head of the calendar are all that is necessary to make it clear.

I note also in Kennedy's calendar that he takes no account of the fact that previous to 1662, when the English liturgy was revised, the extra day in February was inserted between February 23rd and 24th, which practice extends back to the time of Caesar. My calendar provides for these exceptional days.

W. J. SPILLMAN,

Washington, D. C.

KENNEDY'S CALENDAR.

1. Takes no account of place of intercalary day previous to 1662. (Between February 23rd and 24th).

2. Contains errors throughout. Example:

			Kennedy	True day.
October	12th,	192 (O.S.)	Wednesday	Thursday
October	12th,	292 (O.S.)	Monday	Wednesday
October	12th,	392 (O.S.)	Sunday	Tuesday
October	12th,	1092 (O.S.)	Monday	Tuesday
October	12th,	1292 (O.S.)	Friday	Sunday
October	11th,	1492 (O.S.)	Monday	Friday
January	10th,	372 (O.S.)	Sunday	Tuesday
January	10th,	572 (O.S.)	Wednesday	Sunday
[illegible]	[illegible]	672 (O.S.)	Sunday	Friday
[illegible]	[illegible]	972 (O.S.)	Wednesday	Wednesday
[illegible]	[illegible]	1114 (O.S.)	Saturday	Sunday
September 2nd,		1752 (O.S.)	Thursday	Wednesday
September 14th,		1752 (O.S.)	Thursday	Thursday

The following letter received from Mr. Kennedy explains some of the discrepancies that have been found in the use of his tables:

"The table is absolutely correct, but there are two slight errors in the examples given, which require correction.

1. "Example 1," your proof-reader has inverted the figures "89" making it read "98."

2. "Example 3," is my oversight. "In century table opposite O" should read, opposite "1", for the beginning of the century was January 1st, 1. Then follow this by "which is *6*," added to 1 gives Saturday, instead of "Friday."

The Christian Era began on *Saturday* instead of "Friday."

None of the readers of the SUPPLEMENT seems to have detected this, and I am interested in having these little errors corrected

S. F. KENNEDY.

PERPETUAL CALENDAR

To find the day of the week of any date: find the year; proceed thence up the column to the month; the line of week days opposite applies to that month. Example: Jan. 5, 1915; the year 1915 occurs in the last column (at extreme right). In this column the month of January occurs opposite the line of week days beginning with Friday. Hence Jan. 1, 1915 is Friday, and Jan. 5 is Tuesday.

Leap years occupy 2 columns. For dates in Jan. and Feb., leap years are to be regarded as belonging to the 1st, and for later months the 2nd, of these two columns.

The table of years covers 4 centuries. Years in other centuries are brought within the limits of the table by adding or subtracting any exact multiple of 400 yrs. Thus the year 1492 would occupy the same place as the year 1892; the year 412 the same place as 1612, &c. Old Style dates must first be converted to New Style (see conversion table).

The Gas from Blast Furnaces—IV*

Its Cleaning and Utilization

By J. E. Johnson, Jr.

Concluded from SCIENTIFIC AMERICAN SUPPLEMENT No. 2042, Page 127, February 20, 1915

METHODS OF DETERMINING THE AMOUNT OF DUST IN BLAST-FURNACE GAS.

A METHOD employed with good results in Europe for determining the amount of dust in the gas consists in drawing a definite quantity of the blast-furnace gas to be tested through a filter, which is weighed in a dry condition before and after the test. The apparatus for determining the amount of dust consists of a glass tube drawn out at one end and fitted at the other with a ground-glass cover which is also drawn out to a thin tube. This cover facilitates the placing of the filtering material in the tube, and during the test the cover

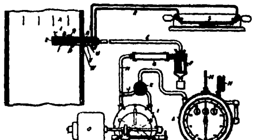

Fig. 30.—The Brown dust, moisture, and volume determinator.

is fastened to the tube by means of wire. Before the test, the glass tube, filled with suitable filtering material is placed in a drying furnace and heated at a temperature of 105 deg. Cent. until its weight is constant, which usually requires from 1 to 2 hours. The drying furnace is arranged so that several tubes can be dried simultaneously.

During the drying process air is drawn through the tubes after having previously been thoroughly dried by passing through bottles containing calcium chloride and concentrated sulphuric acid. During the drying process the tubes are weighed until no further increase in weight is observed.

In making the test, the weighed tube containing its filtering material is inserted into the gas main, a rubber stopper keeping the test-hole tight. The upper end of the tube is connected with a gas meter, which in turn is connected with a barrel filled with water. The water is allowed to flow out of the barrel and in so doing creates the necessary suction to draw the gas through the filtering tube and through the gas meter. When the necessary amount of gas has been withdrawn the tube is again dried and weighed. The increase in weight decrease the amount of dust in the quantity of gas tested.

BROWN DUST, MOISTURE, AND VOLUME DETERMINATOR FOR BLAST-FURNACE AND OTHER GASES.

This apparatus has been devised in order to accurately determine the amount of dust and moisture contained in blast-furnace gas, as well as the volume of the gas, and is used with considerable success.

Referring to the accompanying drawing, Fig. 30, *A* is a gas main conveying the gas to be tested. *B* is an aperture in the small pipe through which samples of the gas are drawn. *C* is a filtering medium within which the solid constituents of the gas are deposited. *D* is a conduit leading to the exterior of the gas main through which the filtered gas is conducted. *E* represents a flexible connection to a surface condenser, *F*. *G* represents a receptacle for some chemical, such as calcium chloride, which can be used for the purpose of taking out the moisture contained in the sample. *H* is a conduit from this moisture-removing receptacle to the rotary air pump, *I*, or through the by-pass *J* to the three-way valve *K* and thence to the gas meter *L*, where the volume of the sample is determined, together with its temperature and pressure; these latter by means of the thermometer *M* and the U-tube *N*, respectively. An electric motor, *O*, is used to operate the pump *I* through the variable-speed drive *P*.

An indication of the velocity of gas or gases in conduit *A* is transmitted through aperture *Q* in the sample pipe and conduit *R* to horizontal pressure gage *S*; also an indication of the velocity of gas or gases after passing aperture *B*, is transmitted from aperture *T* through conduit *U* to horizontal pressure gage *S*. It is evident that changes of the velocity of the gas or gases in aperture *B* of sample pipe, produced by the suction of pump *I* or by pressure in gas main *A*, are indicated, and can be accurately controlled and made equal to the velocity of the gas or gases in conduit *A*, the gas main, such indicator being the oil piston shown in glass tube forming a part of the velocity gage *S*.

The method of operating this apparatus is as follows: The dry weights of the filtering medium *C*, of the receptacle *G*, containing the calcium chloride, and of the measuring flask attached to surface condenser *F*, are very carefully determined. They are then inserted in the apparatus, and the sample pipe is then inserted in the gas main, a tight connection being made between flange *W* and bushing *V*. The meter reading is noted. At the same time that the sample pipe is inserted in the gas main *A*, the time is noted, and the rotary pump *I* started. The speed is then so regulated that the oil piston in the horizontal pressure gage *S* is maintained in equilibrium. This indicates that the velocity in aperture *B* is exactly equal to the velocity in gas main *A*, this condition having been determined by a measured amount of gas in gas main *A*, and the proper proportioning of aperture and conduits in the sample pipe during the calibration tests. This condition is maintained for an definite length of time and the sample pipe is then withdrawn from gas main *A*. The meter reading, multiplied by the ratio of area of aperture *B* to area of gas main *A*, gives the total amount of gas passing through gas main *A* in the elapsed time. The difference between the dry weight of the filtering medium *C*, before and after the test, divided by the number of cubic units shown by the meter, gives the weight of dust per cubic unit. The moisture per cubic unit of gas is found in a similar manner from the sum of the weights of the water in drying receptacle *G*, the water caught in the measuring flask attached to surface condenser *F*, and the weight of water retained in the filtering medium *C*.

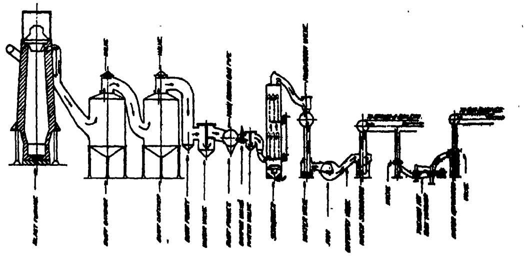

Fig. 31.—The course of the gas through the cleaning process to stoves, boilers, and engines.

Figs. 31 to 34 are reproduced from Mr. Diehl's paper as showing approved types of construction. The text of Mr. Diehl's concerns itself principally with operation and will be quoted in dealing with that subject.

In addition to the processes so clearly described by Mr. Forbes, there are various others designed to remove the dust from the gas in the dry state, but as these have had no extensive application for the blast furnace process, they may be omitted here.

Even since the time of Mr. Forbes' paper there has been an extensive development in Europe of the Halberger-Beth process of which there are now almost thirty plants in use in Europe and the number has been rapidly increasing. American furnacemen have been slow to take up this process and have acted in this matter along the same line as in many other cases; where an apparatus requires careful supervision or where its maintenance charges are high, operating economies secured by its use are disregarded. The same has been true in regard to the gas engine, by-product coke-oven and many other kinds of apparatus.

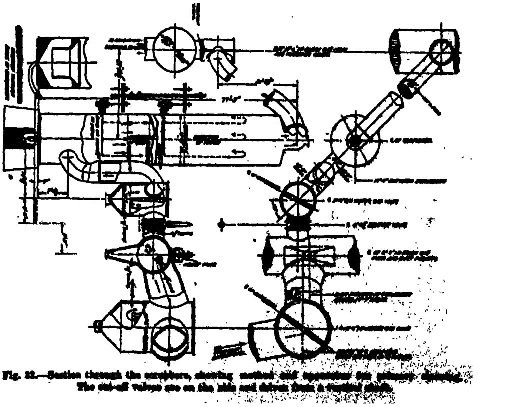

Fig. 32.—Section through the scrubbers, showing method and apparatus for primary cleaning. The cut-off valves are on the side and driven from a vertical shaft.

* Reproduced from *Metallurgical and Chemical Engineering*.

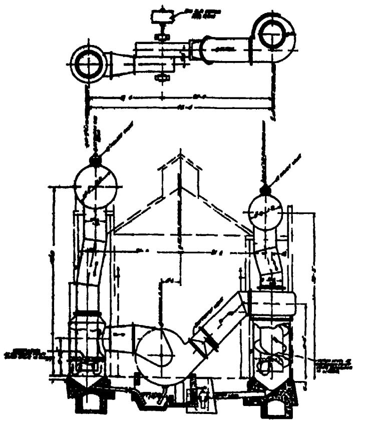

Fig 33.—Section through fans, and method of passing gas through seals and separators.

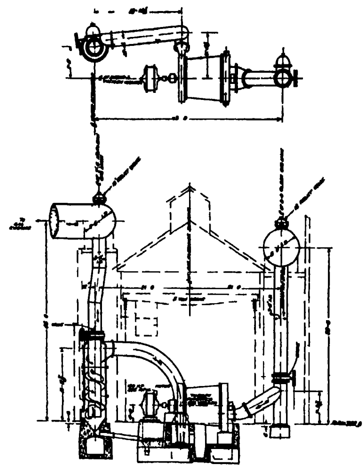

Fig 34.—Section through Theisen's seals and separators showing course taken by the gas.

This attitude is one often censured not only by foreigners, but also by Americans who do not consider all the aspects of such problems particularly the financial one The relative cheapness of capital and supervision and the costliness of raw materials in Europe as contrasted with the high cost of capital in America and the low cost of raw material constitute in no small measure a justification for the American attitude

There is reason to hope that a process may soon be developed superior to either the wet processes or bag filtration plant and less complicated and difficult of maintenance I refer to the Cottrell process for the electrical precipitation of the dust by a high tension direct current passing through the gas column This process has been developed to complete success in several lines of industry but its sponsors have hesitated to attack the blast furnace problem on account of its size and the complexity of the conditions If this process shall ever be worked out to a commercial success it will furnish gas absolutely clean with no loss of temperature and with no increase in its moisture These are the ideal conditions for the use of furnace gas for combustion purposes For the gas engine it must in any event in present practice be cooled about to atmospheric temperature and this of course can easily be done after the gas is removed by a direct spray Perhaps the time might even come if hot cleaned gas were available that the gas engine could be adapted to its use and thereby further increase its economy

In conclusion it may be said that it is impossible at the present time to write a history of gas cleaning The whole development of the subject in this country covers barely 10 years in all and nine-tenths of it has been in the last 7 or 8 years The advantages have become manifest and all furnacemen have sought a way rather than *the* way to clean the gas and undoubtedly they were right in this course for the plants installed early even though not the last word of perfection in the subject will have paid for them less in bettered operating conditions before the much to-be-desired best method is developed It is possible therefore with this rapid development in progress to give only an outline of the subject and to state briefly the principles which underly its application To this has been the attempt of the present article

Mathematics and Artillery Science

At a recent meeting of the Mathematical Association in London Sir George Greenhill made a remarkable address in which he brought out strongly the relations of science to war and particularly emphasized the almost hopeless position of a country that is supinely content with the systems of a century ago. America might learn a useful lesson from the following abstract of the address derived from the London *Times*

Sir George Greenhill said that less than six months ago the artillery officer would have said there was no such thing as mathematics in artillery science. But that outlook was now ancient history This was a mathematical war Drawing upon his experience as a professor of artillery theory for instances where science could prove itself useful on service, he explained how particulars of the enemy's guns could be deduced from fragments of the wall of a shell and photographic pictures. From a fragment they could determine whether a shell came from one of the 42-centimeter howitzers, the very existence of which still appeared in doubt. Dealing with the calculation for ascertaining how far men should stand from a gun to avoid the danger of permanent deafness, he said they need not fear to stand twelve yards behind the 42-centimeter howitzer and so the story was discounted of the firing party taking cover 200 to 300 meters away when this howitzer was fired. An application of the theory of the conduction of heat would have reassured our men that life in the trenches would not be too cold, or would at least be warmer than in the front line, provided only the floor could be drained dry under foot. It had also to be borne in mind that the trench gave better cover than a tent.

Nine years ago he had an invitation to Berlin, to visit the Military Technical Artillery Schools. It was a magnificent [illegible] such as we could not afford, as our [illegible] should bear in his department no money was spared in recent equipment including a bomb-proof range available for artillery fire and yet in the heart of a big city There were plenty of outdoor artillery ranges also to visit, where instructive work was in progress The Ferry system of education was adopted in Berlin After a lecture on wireless telegraphy the class was set to work as he saw in making the antennae which had played such an important part in the war Sixty officers were under instruction at a time for a course of three years, and he was assured their zeal was admirable It was considered such bad form not to give the best in return for the honor and glory of the Fatherland. But our Regular was apathetic by comparison. We must put our trust in the junior ranks to push old Apathy from his stool and carry us through this war

MOURNFUL CONTRAST AT WOOLWICH

It was a mournful contrast to revert to Woolwich, shabby and undisciplined There they had been evicted from their proper home, and were told to found a new artillery college with the choice of a cellar under some stables or a kitchen and scullery and bare walls in a deserted hospital, there to organize victory and at no expense With the courage of an Austrian general compelled to maintain his muzzle-loading musket a match for the Prussian needle-gun, the Military Director assured them that there was nothing superior to be found at Greenwich, in the Naval College there lodged in the old Palace. Such dismal, penurious surroundings had a disastrous effect on the *genius loci*, and they never really recovered from a downhearted spirit not calculated for victory Our military science was under the rule of Thumb, the official genius. His fumbling method was considered a match for disciplined theory

We saw already how the cost had been well laid out in this war of the Berlin Military Technical Academy, the Germans jumping off with a lead he was able to keep as far [illegible] article of the academy was employed in [illegible] dissemination of true theory and in the scientific direction of warlike preparation as at Krupps Assuming everything for the best for the Allies and if we lived to go in again at Antwerp an interesting match would be watched between our artillery science and the German to see how long it would take us to get the other side out compared with our own innings and the time we kept our wicket up No long range fire, he had been assured was ever going to be of any use again involving theoretical calculation The word was Gallop up close to 400 yards and let them have it.

The country was furious at the way our poor fellows were pounded mercilessly at the start by long range accurate howitzer fire with no protection from our own side King George's stirring appeal Wake up England, was intercepted by our rulers, and it was England the unready again when our senior lethargy bumped into the titanic energy of the German Empire

Light, Power and Irrigation in California[1]

Hydro-electric plants have reached a high state of development in California. At present there are 110 reservoirs with a storage capacity estimated at 235 780 000 000 gallons and the plants served produce a million horse-power in electric current which is used for light and for power not only for running car lines but in factories as well In many cases the current has to be carried great distances from the generating plants to the place where it is used and as high as 150 000 volts are carried on some of the lines One most useful feature that has been developed in planning some of the California plants is the utilization of the water after it has done its work in producing electricity for irrigation and where this cannot be done directly it has in some cases been found feasible to use electric power to pump water for irrigating what would otherwise be unproductive lands.

NEW BOOKS, ETC.

SMITHSONIAN PHYSICAL TABLES. Sixth Revised Edition. Prepared by Frederick E. Fowle, Aid Smithsonian Astrophysical Observatory. Washington: The Smithsonian Institution, 1914. Price, $2.

We greet with pleasure a new edition of this invaluable collection of tables. The meteorological tables first issued by the Institution in 1852, and primarily compiled to meet the needs of meteorological observers, received such a cordial acceptance at the hands of physicists in general that the volume was followed by three others, dealing respectively with geographical, physical, and mathematical tables. Each of these books presents independently the latest knowledge in its particular field, and together they form a homogeneous series. The fifth and sixth revisions of the physical tables gave opportunity for the consideration and inclusion of much new data, and many governmental and other authorities have contributed to the improvement of the work. The tables have been very carefully rechecked, typographical errors eliminated, certain tables amplified, and not a few entirely new tables added. To Roentgen rays and to radio-activity entirely adequate space has been accorded. All the usual compilations presenting logarithms, strength of materials, compressibility of gases, liquids and solids, sound velocities, and terrestrial magnetism, are of course to be found, and with these a wealth of calculation relating to subjects in less frequent use, such as musical scales, aerodynamics, light-efficiencies, explosives, and magneto-optic rotation. Every physicist should hold this as one of the most useful volumes of his working library.

THE YOUNG MAN'S CHANCES IN SOUTH AND CENTRAL AMERICA. A Study of Opportunity. By William A. Reid. Washington: Southern Commercial Congress, 1914. 12mo.; 173 pp.

A most timely and vital discussion is this study of present-day opportunity in the logical field of our future activities. It is endorsed in a few words of sincere appreciation by John Barrett, director general of the Pan-American Union, with whose staff the author has held an important position for some years. There has been a dearth of just such intimate information as is conveyed by his thoughtful papers, and our young men of worthy ambitions to whom the papers are addressed may learn from them not only of Latin-American opportunities, but also—what is of almost equal importance—of the pitfalls to be avoided. It is pointed out that to take advantage of Latin-American needs it is not always necessary to reside in South America. Periodical travel and a careful study of requirements will often serve quite as well. Mr. Reid discusses positions and openings in agricultural, engineering, and commercial enterprises, presents factors in development as recognized by competent authorities, tells us what the Latins say of themselves, and gives the names of many firms employing North Americans. To youthful, strong and progressive spirits whose eyes are turned southward this series of studies may be followed to great advantage.

STUDIES OF TREES. By J. J. Levison, Forester to the Department of Parks, Brooklyn, N. Y. 8vo.; x, 253 pp.; 156 text figures and half-tone plates. New York: John Wiley & Sons, 1914. Price, $1.60.

This book is intended for the use of the teacher of nature studies and the student of elementary forestry. Although there are several other excellent popular works which deal with this same general theme, Mr. Levison's book is much needed and will be eagerly welcomed by many who are interested in the identification, structure, habits, and uses of our most common trees. The book is divided into nine chapters dealing with identification of trees; their nature, habits and growth, insects and diseases which attack them; their grouping and planting; the pruning and care of trees; the characteristics of the commercial woods; the care of the wood lot, and a general consideration of the study of forestry in its many aspects. In the identification of trees, for instance, stress is laid on some one character that stands out prominently and distinguishes the tree at a glance from all others and in all seasons of the year. Possible confusion with other trees of similar appearance is prevented through careful comparisons which bring out the peculiarities of each species. In these respects the book is unique and is different from any other now available. The discussion of the planting and proper care of trees and of the fundamental principles of forestry, based upon the author's experience of over eight years in the Department of Parks, Brooklyn, N. Y., and in the United States Forest Service, is thoroughly up-to-date and reliable, and will be found suggestive and usable in the highest degree. It is especially recommended as meeting the needs of farmers and others having the care of estates and woodlands, and of students in short or elementary courses in agriculture and forestry. The treatment is concise, systematic and free from an undue use of botanical terms. The author's aim throughout is to give only the salient points and to so present his text that the reader is enabled to reach at a glance, the main features of the subject under discussion. While this book is intended to offer a general and elementary résumé of the whole subject of tree studies and will probably be read chiefly by teachers interested in nature work in schools, nevertheless its readable style, choice and arrangement of subject and emphasis laid upon accuracy, cannot fail to commend the publication to trained foresters and others.

ECONOMICS OF EFFICIENCY. By Norris A. Brisco, A.M., Ph.D. New York: The Macmillan Company, 1914. 12mo.; 385 pp. Price, $1.50 net.

The literature of the new efficiency grows by leaps and bounds. Defining the aim of the new era as the elimination of waste, Prof. Brisco sets forth the latest knowledge pertaining to the reduction of expenditure in energy, time and materials. The underlying principles are exposed, their importance demonstrated, and their operation simply explained for the benefit of the business man. Organization and coordination in the industrial world is considered from different standpoints. Methods of handling men are debated upon, and the hiring of labor—a science too frequently neglected—is the subject of some sensible suggestions. The policy of receiving applicants only when a vacancy occurs is strongly condemned. Habits, fatigue, training and environment, all come within the scope of the work. The chapter on wages and wage systems will be enlightening to many employers hitherto content to jog along the beaten track. Test questions and bibliographies give the work a text-book value.

ELECTRIC-LIGHT FITTING. A Treatise on Wiring for Lighting, Heating and Other Domestic Uses to which Electricity can be Applied, and the Laying Down of Small Private Installations. By S. C. Batstone, A.M.I.E.E. New York: The Macmillan Company, 1914. 12mo.; 317 pp.; 238 illustrations. Price, $1.50 net.

Here is one of the most attractive presentations of the subject we have seen. The laws and the units of measurement are very clearly explained by means of simple analogies. The various accessories of lighting are before us in the clear line drawings of the book, and their aid is continued into the layout of circuits, house wiring, and the equipment of complete private plants. The text is concluded with the rules laid down by the Institution of Electrical Engineers, which were framed with a view to satisfactory results in the use of low-pressure energy not exceeding 250 volts.

RESISTANCE OF MATERIALS. By S. E. Slocum, B.E., Ph.D. New York: Ginn & Co., 1914. 8vo.; 210 pp.; illustrated. Price, $2.

A noticeable feature of this text is the employment of the principle of moments to the exclusion of calculus processes. This, of course, means simplicity in exposition. The necessity to await the completion of a course in the calculus is obviated, and the student is enabled to enter upon the mechanism of materials at an early stage. In trade schools which omit the calculus this advantage will be at once apparent. Principles and practice have been so skillfully interwoven that their knowledge is simultaneously acquired. Engineering applications supplement the text, and answers to problems are bound with the book.

THE WAR AND AMERICA. By Hugo Munsterberg. New York and London: D. Appleton & Co., 1914. 12mo.; 210 pp. Price, $1 net.

Anything from the pen of Hugo Munsterberg is illuminating and of great interest; and although many of the American readers of this work will not subscribe to some of its sentiments, they will find it well worthy of purchase and careful reading. The work discusses the essential factors and issues in the European war and their meaning and import for America. The author believes that the hour for an impersonal account of the war has certainly not yet come and may not come for a long while; and that what our time can contribute is the reflection of the great war in the minds of individuals. Since Prof. Munsterberg's life has brought him into close contact with much which is essential to this war, he believes that this study may help toward a better understanding of facts and feelings which are easily misunderstood in America. "Whatever more the struggle may bring," says the author, "refers to outer events, to the harvest of the guns, to victory or defeat. It cannot change the issues with which these pages have to do. They do not speak of soldiers and strategy and the chances of the battlefield, they speak of right and wrong, they speak of eternal values." The general drift of the book may be determined from the heading of the chapters, the first of which is entitled "The Aggressor." Following this are chapters on "The Anti-German Sentiment," "The German-American," "Threatened Provinces," "The English," "Philosophers," "The Russians," "The German Policy," "The Kaiser," "The Silent Voices," "The Americans," and "The Morals of the War."

THE WAR IN EUROPE. By Albert Bushnell Hart, Professor of the Science of Government, Harvard University. New York and London: D. Appleton & Co., 1914. 12mo.; 254 pp. Price, $1 net.

Prof. Hart has written this book in the belief that other Americans besides himself might be interested in a brief but systematic statement of the resources, aims and difficulties of the European powers; the manner in which they became involved in the war; and the probable result of the struggle to America and to the rest of the world. The work is based on personal acquaintance with all the countries at war except Russia, and the Scandinavian countries. Much of the matter results from studies begun 20 years ago in the universities of Freiburg and Berlin and the École des Sciences Politiques in Paris. The book is intended to be a study of facts, conditions and probable results, and is not intended as an argument. The notable chapters in this volume are those on "The Significance of the European War," "The Six Great Powers," "International Rivalries and Strains," two chapters describing the war in the Balkans and how that war became European, "The Psychology of the War," and the effect of the war on the United States and its probable outcome.

THE WELLCOME PHOTOGRAPHIC EXPOSURE RECORD AND DIARY. U.S.A. Edition. New York: Burroughs Wellcome & Co., 1914. 281 pp.; illustrated. Price, 50 cents.

The Wellcome Diary for 1915 comes to us in the same attractive makeup that has become familiar to us. As a reference and note book for the photographer it has many features to commend it. The sliding-scale exposure calculator attached to the inside back cover is, of course, in evidence as usual. Timely hints and useful tables abound. There has even been found room for a frontispiece in color—a blue hyacinth—which is an exceptionally charming bit of work.

MOTOR-CYCLE PRINCIPLES AND THE LIGHT CAR. By Roger B. Whitman. New York: D. Appleton & Co., 1914. 12mo.; 281 pp.; illustrated. Price, $1.50 net.

Many readers have a grateful recollection of Mr. Whitman's "Motor Car Principles." In this later volume he takes up the timely subject of the motor-cycle and the light car, stating very clearly the essential differences between the latter and the standard type of automobile, and analyzing in detail a representative light car. Motor-cycle engines and their accessories are very thoroughly covered, with gearing practice, cooling, lubrication, carburetion and ignition. Construction details of the different types are not gone into, the author taking it for granted that, once principles are well understood, their application to variant types is an easy matter. The chapters on care, maintenance, and the causes of trouble are illuminating and full of practical help, and the work is worthy of warm appreciation from any interested in either of the motor vehicles with which it deals.

OPTIC PROJECTION. By Simon Henry Gage and Henry Phelps Gage, Ph.D., Ithaca, N. Y.: Comstock Publishing Company, 1914. 8vo.; 731 pp.; illustrated with plates and with more than 400 text-figures. Price, $3.

Here we have a science that has lately made such strides in popular appeal, and which promises so much in the educational field by its graphic impartation of knowledge to a large number of persons at one time, that such a broad and yet explicit work as "Optic Projection" should immediately find a wide circle of students. All kinds of projection apparatus and all methods of lighting are presented. The magic lantern, opaque projection, and the preparation of slides are most fully dealt with. The projection microscope, drawing and photography by means of lantern and camera, and moving pictures, are all explained by the profusely illustrated text. There are chapters on the room and the screen, electric currents and their measurements, the optics of projection, and the use of projection in physics. In a word, apparatus of various forms and using various methods of lighting, are considered from the standpoints of the operator, the manufacturer, and the student. Certain faults in present-day manufacturing practice are pointed out, and remedies suggested.

FUNDAMENTALS OF PLANT BREEDING. By John M. Coulter, Ph.D. New York: D. Appleton & Co., 1914. 12mo.; 347 pp.; illustrated. Price, $1.50 net.

The increase of population in excess of food production creates a problem that becomes more and more insistent with the passing of the years. Science is gradually acquiring a knowledge that makes possible a revolution in plant culture. The author of the volume in hand presents and summarizes this knowledge in intelligible language. From theories of natural selection and mutation he passes to a consideration of reproduction and culture, reviewing recent work in genetics and explaining the role of hybrids. The securing of drouth-resistance and of disease-resistance is studied. Forestry and its methods is adequately dealt with, and there is a short account of what the Government is doing for agriculture in general. The soil in its relation to plants is a most important consideration, and this is reserved for the final chapter. Altogether the work is very timely and acceptable, and presents its subject in a capable manner and from a positive point of view.

AUTOMATIC TELEPHONY. A Comprehensive Treatise on Automatic and Semi-Automatic Systems. By Arthur Bessey Smith, E.E., and Wilson Lee Campbell, E.E. New York: McGraw-Hill Book Company, Inc., 1914. 8vo.; 407 pp.; illustrated. Price, $4 net.

As a subject that is receiving much attention, and toward which much experimental work is being directed, automatic telephony is rapidly building up a literature of its own. Automatic or semi-automatic systems have already been adopted by many governments and as a natural consequence there is an increased demand among telephone engineers for a wider and deeper knowledge of the principles and practice. The authors, in hand, endeavor to meet this demand [illegible] typical circuits [illegible] for the more important systems now in use. [illegible] subscribers' station equipment, measured service equipment, and [illegible] distributor installation, are chapter-headings that indicate the comprehensive nature of the work. The systems of the larger American companies are clearly described, and a final chapter on development studies will prove especially useful and suggestive to students. The many diagrams and inserts lend clarity to what is a somewhat intricate subject.

LAKTRIK LIGHTING CONNECTIONS. With Introductory and Explanatory Notes by W. Perren Maycock, M.I.E.E. London, England: A. P. Lundberg & Sons. Price, 7d.

"Laktrik Lighting Connections" is a vest-pocket booklet describing modern tumbler-switch controls. Numerous diagrams and concise explanations abound. Single-switch control is designated as a survival of the "bad old days of use," and combination installments are urged.

SCIENTIFIC AMERICAN SUPPLEMENT

Founded 1876

NEW YORK, SATURDAY, FEBRUARY 27, 1915

Charles Allen Munn, President
Frederick Converse Beach, Secretary
Orson D. Munn, Treasurer
All at 361 Broadway, New York

Entered at the Post Office of New York, N. Y.
As Second Class Matter

The Scientific American Publications

Scientific American Supplement (established 1876) per year	$5.00
Scientific American (est. 1845) "	[illegible]
American Homes and Gardens "	[illegible]

The combined subscription rates and rates to foreign countries including Canada, will be furnished upon application.

Remit by postal or express money order, bank draft or check

Munn & Co., Inc., 361 Broadway, N. Y.

The purpose of the Supplement is to publish the more important announcements of distinguished technologists, to digest significant articles that appear in European publications, and altogether to reflect the most advanced thought in science and industry throughout the world.

HOW THE GOVERNMENT KEEPS OUR RIVERS FREE FROM OBSTRUCTIONS.—[See page 149.]

Personal Biologic Examinations*

The Condition of Adequate Medical and Scientific Conduct of Life

By George M. Gould, M.D.

The ranchman has his annual round-up: the merchant his yearly account of stock and balancing of books, the machinist gives his engine a thorough going-over at regular intervals; every military organization has its reviews and inspections, every government its budgets—indeed, every financial hair of the commercial head is noted, and not a sparrow of the hunter, Success, falls to the ground unnumbered; those that do not fall are even more accurately numbered. But it is not so concerning the one piece of mechanism that conditions all these things, and that is the most valuable of all earthly possessions—the human body. For all practical consideration a man's body is his life, and yet civilization has come so far without any systematization of the business and mechanics of the entire single and personal life. The science of bodily living in its complete extent still awaits its discoverer. Numberless philosophers treating of the conduct of life have soared in superficial inexactness and easy generality over the heads and hungers of the individual liver, but they have utterly failed to formulate the physiologic and pathologic conditions of success and failure. All the biologic and medical special sciences have struggled toward an unreached unity; all are simple rays, as it were, awaiting the lens of a focalising intelligence to illumine the concrete image of our total physical appearance here. War has devised a rough and crude system of physical examinations for the would-be soldier; insurance companies have more accurately examined the bodies and life-prospects of their policy-holders to estimate their financial risks; through the Bertillon system, criminology has still more perfectly fixed the anatomic measuring of the bodies of the law-breakers; the Amherst and Harvard examinations have looked into the muscular functions of a few students for four years of their lives; the psychophysic laboratory has measured a few neurologic reactions; the medical practitioner has found out a few ways of reaching backward to the etiology of some single diseases; a few hundred school children have been subjected to some tests as to growth and the influence upon organization of poverty and wealth. But all these, I believe, are sporadic and ineffectual hints of a coming science of man, based upon a thorough-going and repetitive system of physiologic and pathologic examinations which will ultimately give us a genuine and all-comprising science of anthropology based upon all the data, morphologic, physiologic, and pathogenic, of the entire individual life. Prophecy and prognosis are based upon a thorough knowledge of the past and present fact, a right understanding in a scientific sense of the evolution of the organism and of its present departures from a normal standard. For his children a foresighted man must wish such an accounting, such a prophecy and prognosis; and as to himself every intelligent adult, when he awakens to scientific consciousness, must try to look forward through the years, and reckon up his powers and possibilities of life. This most important function of prevision has heretofore been left to the gypsies, the palmists, the astrologists, and the clairvoyants! Is it a wise way for science to leave the individual struggler, unconscious and ignorant of his own body and its fateful laws, incapable of learning the scattered and ununified half-sciences blindly converging to some far-off unity of mutual helpfulness and life? The crowning work of scientists is to turn science into prescience. The unification of the sciences dealing with the conduct of life; the making practical and useful our knowledge of the individual organism; and lastly to establish a scientific prescience—such are the ideals of a living anthropology.

Is it not at once plain that these ideals can be realised only by a system of periodic examinations and records made every year or every five years, throughout the life of the individual organism? Such a system of records may be held generally to comprise the following elements:

1. *The Hereditary Datum.*—The endowment at birth, the influence of heredity, must in every way govern and condition the development of the organism, and modify every reaction to environment. It is wise, therefore, in all ways possible to fix, at the opening of life, what is this datum of inheritance. Nationality, ancestral and genealogic histories, craniology, cerebrology, etc., help to make up the estimate of this one factor.

2. *The Development and Historic Record.*—Especially during the period of growth—childhood and adolescence—should the space between the annual or quinquennial systematic examinations be historically epitomized. The strains, work, illness, and tasks conquered or incomplete, are surely a necessary part of the life-chronicle.

3. *The Morphologic or Anthropometric Examination is Fundamental.*—In this the Bertillon system, modified, perfected, and expanded, or something similar, should form the basis of such a system of physical measurements, descriptions, and records, statistic and graphic, that any future variation of the organism would be detected in later examinations; and thus would be preserved the morphologic picture of the individual for the whole life.

4. *The Physiologic Record* would include the testing and tabulation of all the significant reactions and functions. These would be made up of all necessary dynamic tests of the muscular system; of statements of accurately observed metabolic and nutritional functions; the reactions and reflexes of each of the special senses, and of those of the neurologic and psychophysic systems. The profound influence of habits, both positive and negative, innocent or harmful, should also be remembered.

5. *The Psychic or Intellectual Datum* is one too carelessly ignored in scientific and anthropologic studies. The fundamental qualities of character, disposition, memory, sentiment, religion, reason, morality, education, etc., are powerful influences acting upon and reacting to the environment and to disease, and if they are left out of the count a most valuable determinant of scientific prescience is lost.

6. *The Pathologic Element* is one heretofore almost or utterly ignored in anthropologic studies, and in instructions as to the conduct of life. The profession should urge its profound importance. The examinations at stated periods should in large part consist of the records of the findings of expert medical specialists secured by all the arts and instruments of diagnosis at their command. All departures from health and normality that indicate pathologic results or tendencies in any organ, or in the organism as a whole, are absolute conditions of estimate as to present powers or prospects. One is almost inclined to think that the savings in medicolegal cases, by such a system of examinations, would defray the expenses of making them. Some time ago a railway company, after several years of legal proceedings, was forced to pay a man $10,000 damages for intracranial hemorrhage said to have been caused by a fall from a car. When the man died there was found in his brain a bullet which had been received 25 years previously in the Franco-Prussian war, and this had produced all the non-feigned symptoms for which the railway had to pay.

7. *The Factor of Heredity* closes the circle, with the possibility of making more accurate the knowledge of the transmission of the individual endowment to the child. Successive generations are but the completion and extension of a single personality. The family is the realization of the incomplete individual.

Leaving out of consideration the questions of the onerousness of the task proposed, and the apparent impossibility of carrying out so many observations, one may ask as to the feasibility of keeping the records of such a series. The answer to this query points to the most remarkable plasticity and adaptability of the modern plan of record-making by the card system, with its ever variable and extensible use of loose leaflets or cards of different colors, numbers, ear-marks, sizes, etc. Photography, the kromscop, the phonograph, the instruments of the physiologic and psychophysic laboratories, and those of every specialist in medicine, make it easily possible to condense the chronicles of all tests and examinations in an inexpensive and effective way. The post-mortem records, and the preservation of the brains, and, perhaps, of the skulls of the subjects, would supplement the work.

As has been intimated, we already have the beginnings, the sporadic attempts, and detached parts of such a system of examinations. The Bertillon criminal records of the police bureaus, the anthropometric data of military examinations, the results of athletic and gymnasium tests, those of psychophysic laboratories, the medical examinations of school children, and those especially of life insurance companies, etc.—all these indicate the thought, labor and expense which civilization is giving to the problem. But the most important of all contributions might be the case-books, hospital records, and patients' histories of physicians. Hardly a tithe of the precious material, however, is utilized. The waste of biologic data—wasted because not systematized and unified—in the lost records of physicians is appalling. The most valuable books in the world are the oldest city directories, scientific statistic records, etc., and more valuable still would in future years be the present day case books of scientific physicians, if they were well kept and illuminated by statistical and scientific judgment. We now dump them into the pulp-mill.

Is it a foolish dream, is it an unrealizable ideal, that all these things might be preserved, and rendered of use to science and humanity by some institution carried on by the Government, by a university, or by a union of scientific and medical men, whereby the records of individual lives might be made so frequently, so continuously, and so scientifically that we should at least gather the inductive data for a genuine science of anthropology, pathology, and ethical biology? If governments could be prevailed upon to devote to this work one tenth the money now squandered in war; if legislators could be prevailed upon to give to it a small proportion of their stealings and political plunderings; if a fraction of the money poured into the pockets of the ward and city bosses could be got; if a small percentage of that spent on comic opera could be shunted this way! If these are idle dreamings is it not perfectly possible that in future ages some wise legislator of some civilized government may convince his fellows that not only is this the duty of the national administration, but that the very beginnings of the system are already in operation in the national census-taking? In this the mechanism is really inaugurated, and needs but the inclusion of the civil service examination, the soldiers' entrance tests, and the governmental pensioners' medical examinations, to bring it a long way toward perfection. With the plan once determined upon, and the brain once found to gather the haphazard and discrete parts to an organic unity, but little additional expense would be incurred over that now spent in the separate systems. Indeed, the scheme itself is only an extended and a perfected bureau of vital statistics. Once such co-operation were started, the city and State with their criminologic statistics, the insurance companies with their accurate vital and pathologic records, and especially the medical profession with its systematized records of individual and social morbidity, and many other agencies, would be drawn into co-operation, and the bases of a truly inductive and physiologic science of civilization would begin to be laid.

While we wait for that millennial palace of science we physicians need not be idle—nay, we may be at work in the quarries. Our first duty is to reorganise, systematise, and make scientific our case-books and recordings of patients' histories. Let us study this great and neglected art so that these most precious fruits of our life work shall not end in the pulp mill. The lack of literary workmanship in making and keeping our records of disease is altogether deplorable. What is left to science of the life work of a million physicians whose business has been with the most precious biologic facts of the world? Can we not perfect some bridge whereby the results of our life labors can be carried over the stream of death and become the property of general biologic and pathologic science?

Surely then, our second duty is to make our science prescient, by means of the repeated examination at stated intervals of those patients whom we can convince of the necessity and wisdom of such a proceeding. It is a shame of medicine that in the one department of our science which we are most foolishly inclined to look down on with too much superciliousness, its practitioners have outrun us. The dentists have long recognised the need of periodic examinations of the special organ, regardless of symptoms, and they have at last driven the knowledge into the minds of their patients. Thousands of patients have their teeth periodically examined for beginning needs and diseases or to prevent them. If this be wise as regards the teeth, how infinitely wiser it would be as regards the kidneys, the eyes, the heart, arteries, etc., and the person as a whole. It is the shame of medicine and the basis of quackery, this symptom treating and symptom killing. What a horrible fact—this of the vogue of the pain deadeners! Millions of dollars are capitalized in the business, and half or three fourths of the work of

* Presented to the Section on Practice of Medicine, at the fifty first annual meeting of the American Medical Association, held at Atlantic City, N. J., June 5th to 8th, 1900, and published in the Journal of the American Medical Association, July 21st, 1900.

our lives is devoted to the mere stopping or deadening of symptoms. But, as we all know, true medicine is to stop the cause of symptoms, to prevent the symptoms from ever arising. For many years in my specialty, I have been begging that biennial ocular examinations should be made, regardless of "no trouble," regardless of "perfect satisfaction." Absence of symptoms is no evidence whatever of absence of disease. No eye should ever be left over two years without re-examination. No spectacles can remain correct two years, because no eye ever preserves the same refraction, balance, and powers, for that period of time.

And what good also is the enucleated eyeball, or any piece of dead tissue, in the hands of the pathologist? Certainly only to prevent other living eyes and organs from becoming as these dead ones have. True pathology is surely knowledge of the disease in the making. The pathologist's final problem is to prevent pathologic specimens from ever coming into his hands. Qua pathologist he must commit scientific suicide. Most of our fashionable pathology is the paleontology, not the biology, of disease; but was it not said of old, that it is better to be a living dog than a dead lion? How is disease in the making ever to be discovered except by examinations, continuous observation, of the living supposably-well organism?

Is it not even true of living disease that one half the patients seen by the doctor are seen far too late? For paresis, locomotor ataxia, etc., and for many psychic diseases we do nothing, because we recognize their existence so late that nothing can be done. Had they been seen earlier injury could have been prevented. Surely in more than 25 per cent of my patients many years or whole lifetimes of suffering and disease could have been obviated. It is doubtless true in general medicine. All good medicine inevitably tends to become preventive medicine; all good physicians labor to stop disease before it arrives. The whole ingenuity of the trained diagnostician is now expended on the problem of the earlier symptom. He is the greatest discoverer who finds the presymptom, or the symptom of the symptom; the greatest therapeutist is he who cures before the disease exists, he who starves the bacillus to death, he who stops the evil habit, thus preventing the malfunction that becomes organic disease. The best cat is the one that kills the rat that eats the malt that lies in the house that Jack built. It is a truism that gout exists in the patient's system long before it causes a twinge of pain; the kidneys are ruined before the slightest subjective system is manifest; there may be heart changes indicating the existence of nephritis, which a single uranalysis may not detect; arteriosclerosis may be present prior to subjective symptoms, and the objective examination would detect it; there may be unsuspected diabetes without symptoms until examination of the urine reveals it—even with our crude prescience early uranalysis of the apparently well would often reveal the hidden evil at work sapping and mining toward the vital centers. Every oculist has often discovered albuminuria before the general physician suspected it. There are a hundred known intimations and auras of oncoming disease, but there are a thousand undiscovered ones, presymptoms, advance scouts and forerunners, to be learned when the slight and unconscious departures from normality are studied by examinations of the supposedly well. Pathogenesis, not therapeutics, is the ultimate study of all medicine. And all pathogenesis is by no means running bugs to their holes: the greater number of life wasting diseases are not bacterial in origin; and even the growth of the bacterial diseases depends on the soil in which they are sown.

I picture to myself a new field of work opening out before the poor plundered general practitioner. It must often seem to him that as a general he has been stripped of both army and enemy. One by one the specialists have robbed him until he has left hardly a soldier or a patient. The surgeon first took almost half of his army, and now threatens to relieve him of Colonels Appendicitis and Typhoid, and heaven knows of how many more officers which he formerly considered his very own. Then the aurist, the oculist, and the rhinologist deprived him of his special senses, and the laryngologist rendered him aphonic. If the obstetrician and gynecologist left him one or two of all his women folk, the rest cure man and the neurologist soon alienated the affections of these hysterics—and they lived unhappily ever after. The pediatrist stole his babies and the psychiatrist his mind; and, lastly, the gastrologist will not allow him to have all to himself even a simple stomach ache.

The truth seems to be that of all the specialists the generalist has been squeezed into the narrowest specialty, and the surgeon is grasping avidly at his one or two remaining comforts. Even the diseases of the lungs, stomach, and kidneys are now claimed and we may soon expect to see such advertisements in the religious and daily newspapers as: "A new operation for neurasthenia; craniotomy for unselfishness; preventive inoculations in case of threatened breach of promise; vaccinations for antivivisectionists; damaged heart-valves surgically repaired while you wait; kidneys transplanted immediately following the next electrocution; complete maturation of the artificially fertilized ovum in our new twenty-first century incubator."

The family physician's function seems to be fast becoming that of adviser-in-general and referrer-to-others; the "last straw" is that ethics will not permit these others to divide their fees with him. Nothing in fact is left to him except to have permanent anorexia and to move to a climate in which house and clothing are not necessary—Porto Rico and the Philippines, for example—providentially supplied, without doubt, for this and similar tariff purposes.

But seriously, have we not gone too far with our specialism, and are we not thereby in danger of losing the co-ordinating sense and oversight of the organism as a whole? The specialist cannot be dispensed with. By his aid and through his accuracy medicine must progress; but neither should the generalist be squeezed aside. He is even more necessary. It is his duty to teach his under officers, the specialists, their proper places, and by his sane and large grasp of all the facts supplied by these subalterns, by his co-ordination of the work of each and of all with his own overlook of organism and life as a whole, he brings cosmos out of chaos, and organic unity out of hundred-eyed and selfish diversity. The specialist is fatally inclined to treat the disease; to the generalist must be left the far more important treatment of the patient.

It may seem hard and impertinent to say to an audience of generalists that the generalists have been robbed because of their own fault and negligence. The so-called stealings of the specialists are in reality helpful and if rightly understood they leave the generalist his proper work. Life, it has been said, is made up of little things; and yet life itself is not a little thing. So it is with health, fullness of years, and utilization of powers; they all depend, medically and physiologically, upon little things, and yet compositely they are "the greatest thing in the world." In the vogue of the specialist, the generalist is more than ever needed. If the aristocrats have usurped power, there is the chance and demand for a powerful king. The specialists are, or may be made, the assistants of the general physician, who needs their help and all the data they can supply, and whose supreme function it is to fuse the whole to a higher unity and to establish the secret relations in reality existing in all. There is no specialist who is not willing and glad to make full and systematic reports to the general physician of all his findings. It is his duty to the patient and it is the specialist's self-interest to do it well. He is not so stupid as to offend the referrer of patients. In this function the generalist has the whip-hand—and he should use it, at times.

And thus it happens that the desirable system of personal biologic tests sketched need not await the action of government, the university department, the city or State institute, the union of anthropologic societies, or the anthropometric and pathologic institution founded by private endowment. Let us earnestly pray and work for any or all these things; but in the meantime much may be done by medical men and societies to prepare for the larger and more perfect outworking of the scheme—nay much may be done toward the realization of its more distinctively medical features.

Based upon the fact actually felt by every physician, that a series of systematized periodic examinations of patients apparently well would often reveal beginning diseases, prevent future illnesses and increase the vital values of life, every one can prevail upon certain patients, students or members of his family, to undergo the necessary tests. The more intellectual and well-to-do citizens will soon realize the self-evident value of such work, and not only submit to it for themselves and children, but will be willing to pay an annual fee for the service. Specialists will be willing to contribute their results. The examinations need be only of the more fundamental and simple factors at first until the good-will, machinery, funds, and recognition of the significance and usefulness of the work grow.

In several ways these examinations themselves are the means of a striking self-education of the physician:

1. In systematizing and perfecting a method of record-keeping there is a subjectively psychologic as well as an objectively scientific result of inestimable good. It is a sort of liberal education. To adapt and perfect the card system to this useful end; to summarize the results of all diagnostic methods; to formulate prognoses; to classify and epitomize so that the whole shall look to the personal advantage, as well as toward the progress of preventive medicine; and finally, to dovetail the combined result into general biologic science and to clarify the laws of heredity; all of this is labor worthy of the wisest selfishness and the best intellectuality.

2. In rendering accurate and mathematical all the known and recognized methods of medical testings, there is much to be learned. It is in catching sight of the forerunning indication of disease, the symptom of the symptom, the functional beginnings of organic abnormalism, that a great deal of progress lies. Who, e. g., as yet, measures the blow or stimulus in taking the patellar tendon and other reflexes, with machine-shop accuracy, also the resultant excursion or reaction, chronicling same in his notes, with absolute or approximate precision?

3. In the excursions into the border land, but still closely related, domains of cerebrology, craniology, psychophysics, criminology, sociology, public hygiene, and all the rest—in learning to make these tests, and chronicle the results required in these studies, one enlarges the range of his subjects, broadens his personal and scientific outlook, in a word annexes with justifiable imperialism and expansion, the adjacent territories of his special science. Each gives his light, and, as in all beneficence, by giving, each increases his own as well as the general illumination. The stars go out but the day dawns.

Cultivation of Living Tissues Outside the Body*

The story of the cultivation of tissues outside of the living body has already lost much of its novelty. Though we can still easily count the time in terms of months rather than years, since the first demonstration of the development in vitro of isolated fragments made up of connective tissue cells, the fact has been established so conclusively and the technic developed so successfully that the cultivation of tissues in this way has already become a familiar practice in many laboratories. It is sometimes said that familiarity breeds contempt; but it may be wholesome at times to renew our acquaintance with the details of well-known scientific procedures and learn their present status. This is particularly desirable in the case of those persons who little realize the persistence and energy, the patience and forethought, which many of the permanent acquisitions of science demand on the part of investigators. We who share the results all too frequently fail to understand the laborious process by which success is attained. In this field the advice once given to an ambitious medical student may be reiterated: "Success is neither luck nor pull, but the longest, toughest job you ever tackled."

Not long ago Carrel[1] of the Rockefeller Institute for Medical Research called attention to the condition of a strain of connective tissue kept outside of the organism in a condition of permanent life. It was derived originally from a piece of heart extirpated from a chick embryo. The fragment pulsated for 104 days, and gave rise to a large number of connective tissue cells which have since multiplied actively. The strain, after having undergone 358 passages, reached the twenty-ninth month of its life in vitro some time ago. It now appears that the proliferating power has in no wise diminished. During the third year of independent life of the connective tissue we are confronted with the remarkable fact that it shows greater activity than at the beginning of that period, and is no longer subject to the influence of time. Carrel remarks that if we exclude accidents, connective tissue cells, like colonies of infusoria, may proliferate indefinitely.

In this connection it is interesting to note some recent results for human tissues reported from the same laboratory. It has been possible, for example, to keep human fetal tissue, derived from fresh cadavers, in a condition of independent life for several generations.[2] This has led to the attempt to cultivate human sarcomatous tissue in the same manner. The first essay in the direction of growing human malignant tumor in vitro was made in 1911 by Carrel and Burrows.[3] The tissues were kept in a condition of survival for a few days, but no real cultures were obtained. Losee and Ebeling[4] have now succeeded in keeping cultures of such tissue in a condition of active life in vitro for several generations. Their method may, therefore, prove of value in the study of the growth of human malignant tumor.

The full-sized experimental flying-boat with hollow V-shaped hull, at Washington Navy Yard.

Experiments With Flying Boat Hulls

By Carl Hawes Butman*[1]

THE first report of the sub-committee on hydromechanics in relation to aeronautics just published by the Langley Aerodynamical Laboratory of the Smithsonian Institution, deals with the results of a series of experiments with flying boat hulls. The experiments were conducted at the Model Basin in the Washington navy yard under the direction of Naval Constructor H. C. Richardson, for the purpose of determining the resistance of several models at "displacements corresponding to speeds," on the water, and the resistances "submerged," as a means of approximating their total head resistances in air, and of determining an approximate "coefficient of fineness of form."

The experiments proved particularly successful. A form of improved hull has been derived which will probably supersede the present type of naval hydroaeroplane hulls. This model appears to have certain advantages over the types now in use, possessing less resistance on the surface of the water, and less head resistance in the air under similar conditions.

The model hulls used in the experiment were of the ventilated step type, one-ninth actual size, except one a quarter-size model of the original "Curtiss" pontoon. Plots of the model runs were made by the investigators showing: net resistance, derived effective horse-power, and change of level. The resistance curves were determined by towing the models in the basin at "displacements corresponding to speeds," with a set trim, but free to rise or fall under the influence of suction or planing. The change of level curves show how the planing effect changes the draft at each condition. The models were towed under conditions representing a full load of 2,200 pounds, with the assumption that the get-away occurs at a speed of 45 miles per hour. From the curves it is obvious that suction is present at low speeds, succeeded by a condition in which the model runs hard, followed by a period during which the model begins to plane; just before planing is effected, the slope of the curve lessens rapidly, and when planing is established the resistance falls off sharply with one exception.

A model was designed to obviate the defects of the flat scow-bow type, by introducing the V type bottom for parting the water rather than forcing it aside. An earlier model of the V type caused a great amount of spray, and to overcome this the V section was made full but as this only increased the spray, the V sections were made hollow which brought about the desired results: holding the spray down, increasing the planing effect, and reducing the resistance.

Confirmation of the behavior of the models has been fairly well established by the actual performance of full sized machines. Actual experiments with a full sized machine show that the improved hollowed V section hull is very desirable on account of the good landing qualities.

From the experiments carried on it has been determined that the step should be close to the center of gravity, to eliminate the nosing tendency, to facilitate change of trim while planing and to avoid a change of balance when getting away or landing; hollow V sections decrease the spray, cut the water easier and cleaner, plane better, and reduce the shock of landing or running through rough water, practically eliminating the necessity of shock absorbers. A shallow step seems to be sufficient, but ventilation back of the step is essential to facilitate the breaking of suction effects. The bottom forward of the step should be inclined to the axis of the machine but not so greatly as to cause the machine to plane before the controls are effective. The bottom abaft the step should rise strongly to favor a steepening of the planing bow before the elimination of suction, and to get the tail well clear when planing begins.

Diagrams were also made to show the logarithmic plots of the models when submerged one foot and towed at speeds up to 15 knots. From these plots it is seen that the resistances of the models closely approximate the law of the square of the speeds. The head resistances of the full sized machines were calculated by three methods, and vary about 20 per cent. Several other useful values worked out mathematically.

Plans are under way for further experiments on submerged models to determine the stream line flow about the models, as a means of arriving at improvements in form, as well as to calculate the effects of cockpit openings, sponsons, etc., and to study the torque at different angles.

Wheatstone Bridge for Resistance Thermometry

THERE has just been issued by the Bureau of Standards of the Department of Commerce a paper describing a Wheatstone bridge designed with especial reference to flexibility of use in measurements with resistance thermometers and discussing the use thereof. The bridge is adapted to use with either the Siemens type or Callendar type of resistance thermometer or with the potential terminal type of thermometer by the use of the Thomson double bridge method. The instrument is also arranged so that it may be completely self-calibrated.

The accuracy attainable with the bridge is such that resistances of one ohm or more can be measured to an accuracy of one part in 300,000 in terms of the unit in which the calibration is expressed. This corresponds to an accuracy of about 0.001 degree for measurements with the platinum resistance thermometer. Low resistances, the accuracy of measurement of which is limited by variations in contact resistances, may be measured to about three millionths of an ohm. This figure, rather than the one given above for accuracy, represents the precision attainable in measuring small changes of resistance, such as are usual in resistance thermometry.

Snag Boats on Flood Rivers

A Safeguard to Navigation

By Day Allen Willey

Many of the so-called flood rivers in the South and West, flow through channels where the bottom and sides are merely of earth and sand, and when a river is in flood the current washes out the banks, causing woodland, prairie soil, and other formation to be submerged, and, in some instances the surface of the land, to the depth of several feet is carried down stream by the current in the form of liquid mud.

Such rivers as the Mississippi, the Arkansas and the Red River run through swamp lands in some locations which are covered with trees and bushes. In high water trees are often uprooted and float down with the current. When the flood recedes, the trees may be held in the stream channel, the roots sinking into the bottom and remaining in such a position that they form dangerous obstacles to navigation. Often the upper end is but a few feet below the surface, and a vessel moving in line with it may be pierced through its hull and sunk as the pilot is unaware of the "snag."

Where these washed-out trees project above the water, they are almost as dangerous as the sunken snags, as they are often in eddies and cross currents in the channel where a steamboat may be wrecked against them.

The War Department has adopted several methods to free these navigable rivers of snags. An idea which has recently been adopted is to bore holes in the wood, insert dynamite cartridges, and thus shatter them to pieces. The most effective plan, however, is to pull them out of the water and saw them up, sometimes using the pieces for fuel for heating the furnaces of the boats which pull them out by steam.

These snag boats were the idea of one of the army engineers, and the first was built about 10 years ago for service on the Mississippi river. Since then the boats have been enlarged, equipped with more powerful lifting derricks, operated by a steam engine which is independent of the one which propels the boat.

One of the latest types of these floating snag pullers is stationed on the Mississippi river. It draws less than 4 feet of water, and consequently can be operated on shoals and in other shallow spots. Two engines of a combined capacity of 600 horse-power furnish motive power, giving a speed ranging between 5 miles and 6 miles an hour upstream against a strong current.

The double bows are separated by what is termed a well which is 12 feet in width, each bow being 65 feet in length. At the forward end what is termed a "butting beam" extends from bow to bow. This is a heavy steel beam 22 feet in length, 7 feet wide, and no less than 16 inches thick, greatly strengthening the framework of the boat. As the name implies it is used to ram or butt a snag when necessary to dislodge it from the bottom before pulling it out of the water.

Attached to this beam is a sweep chain which drags beneath the water and is designed to grip the lower portion of the snag and aid in lifting it to the surface. This chain is lowered over the bows by a capstan placed at one end, and raised in the same manner. Its purpose is principally to lift the upper end of the snag high enough to permit the butting beam being pushed under it.

Upon the bows are the lifting derricks, one being utilized to pull out small snags after they have been loosened by the sweep chain and butting beam. Those on the sides are intended to pull up obstructions which can be readily removed by means of block and tackle.

On the boat the crew includes a diver whose duty it is to go under water when necessary to fasten the chain around the trunk, or to bore holes in the wood for the dynamite cartridge and connect its detonater with the wire that extends to the electric keyboard on the boat.

Another large snag boat is in use on the Mississippi and tributary waters which is 187 feet in length, 52 feet beam over the hull, and can operate in water 3½ feet in depth. It is also constructed with a hull of steel and iron, and driven by two oscillating engines, steam being furnished by five 42-inch boilers giving it a total horse-power of about 500. The snagging apparatus consists of two pairs of friction capstans placed in the forward hold and six capstans installed on the deck.

The "Suter" carries a butting beam of oak plated with iron, also a series of five iron shear legs in addition to supporting blocks and tackle, a Sampson chain of 2½-inch links, and a sweep chain.

Such is the capacity of these snag pullers for removing the obstructions to navigation that by the service of this fleet one of the greatest dangers to steamers and barges plying on the flood rivers, has been largely abolished.

Diseases Dangerous at Different Periods of Life

Much has been said of late concerning preventable diseases and methods of reducing the annual rate of mortality. The first essential of any such schemes is a carefully prepared summary of the causes of death in a particular country during a specified period, and a statement of the age and sex of those dying within this term of years. For some twenty years the German Empire has published statistical tables of all officially reported causes of death. These have always been divided into periods of life and of late years have distinguished sex. They do not, however, cover the entire population, for the participation of the different states of the empire is voluntary; but there has been a gradual increase until four years ago 96.85 per cent of the inhabitants of the empire were included in these digests. An interesting analysis of the main causes of death at different periods of life, as shown by these tables, is made by Dr. G. Rahts in a recent number of the German journal *Umschau*.

Speaking of infants under one year of age he states that in the decade 1892-1902 the deaths among such infants averaged, during a calendar year, about 20 to 22 of each 100 born alive, and in the five years 1906-1910 only 17 to 18 of each 100. Of late years about 348,000 children die annually in Germany, 332,000 of them dying of known causes. For more than one third of those dying of known causes within the first year the indicated ailment is chronic gastro-enteritis or cholera infantum, that is, the illness arose from unsuitable or defective nourishment. For about one seventh congenital weakness is the stated cause of death, which occurred generally in the first month of life. Other fatal maladies noticeable for their frequency among infants less than a year old were inflammation of the lungs, to which 115 of each 1,000 dying succumbed, and whooping-cough from which about 30 of each 1,000 deaths arose. Tuberculosis, measles, and scarlet fever, taken together, carried off less than 3 in each 100 deaths of young infants, that is, less than whooping-cough alone.

For the period of childhood from the beginning of the second year to the end of the fifteenth year Dr. Rahts finds, in his examination of the tables, that the annual average of deaths was about 111 to 112 per 1,000 living; the annual average during the five years 1906-1910, from which the figures are mainly drawn, was about 140,000 children, of whom 8,300 died of unknown causes. The most important causes of death given for this age per 1,000 children who died are: Pneumonia, 147; other diseases of the respiratory system, 65; tuberculosis, 105; diphtheria (including croup), 92; scarlet fever, 64; measles, 54; whooping, cough, 39; diseases of the digestive tract (including appendicitis and its consequences), 110; accidents, 45.

In discussing the statistics just given, Dr. Rahts says: "According to this in the period from 1 to 15 years life is threatened to a large degree by four widely spread, easily conveyed diseases of childhood, diphtheria, measles, scarlet fever, and whooping-cough, for these four diseases together cause the death of almost the fourth part, 22 per cent exactly, of all who succumb in this period of life. After these, pneumonia, or some other disease of the respiratory system, is designated as the cause of death for fully one fifth, 21.2 per cent of all who die from known causes, and tuberculosis as the cause for fully one tenth. Disease of the digestive tract, including appendicitis, was a somewhat more frequent cause of death than tuberculosis. Lastly, the large number of fatal accidents at this age is noticeable, for about 1 of every 22 cases was attributed to 'death by accident.'"

According to these tables, tuberculosis of the lungs carried off the greater number of those who died in the period between 15 and 30 years of age. During the years 1906-1910 the deaths from this disease were 462 per 1,000 deaths from known causes among women and 375 per 1,000 deaths among men. Other forms of tuberculosis in addition are given as the cause of death for a further 35 per 1,000 deaths. Among those from 15 to 30 years old other forms of disease, as compared with tuberculosis, are much less frequently the cause of death. Among every 1,000 males (females) who died from known causes at this period of life there were: 65 (77) deaths from diseases of the heart or of the blood-vessels; 61 (46) from pneumonia; 33 (37) from other diseases of the respiratory system; 51 (54) from diseases of the digestive tract, including appendicitis.

In continuing his analysis Dr. Rahts says further: "Besides the diseases mentioned, a very frequent cause of death in this period of life is an injury, especially among males. Of each 1,000 cases of death among males no less than 128 resulted from accidents and 67 from suicide, that is, almost 1 in 5 arose from some form of violence. Among females from 15 to 30 years

of age accidents which resulted fatally and suicide were much less frequent, only about 1 death in 22 or 23 being caused among females by such violence. In place of this, however, puerperal fever is frequently mentioned as the cause of death during the youthful age of 15 to 30 years, namely for 30 of each 1,000 females dying."

Tuberculosis of the lungs is also, according to these tables, the most fatal disease in the period of greatest vigor, the age from 30 to 60. Of each 1,000 males who died 222 succumbed to this malady, and 207 of each 1,000 females dying. The next most frequent causes of death in this period were diseases of the heart and of the blood vessels; 150 of each 1,000 females and 135 of each 1,000 males who died succumbed to such maladies. As in the previous period of life, heart troubles seemed to be more often fatal to women than men. In this age of 30 to 60 cerebral affections and spinal diseases become very noticeable as causes of death, for about one tenth of all the men died from cerebral apoplexy or of some diseases of the nervous system, the proportion of women dying from these diseases being not quite so large. In this period of life also cancer and other malignant tumors were a frequent cause of death. Such new growths are more frequent among women than men, being noted as the cause of death for about 3 of every 20 females dying and for about 3 of every 33 males. The large number of suicides and fatal accidents in the age from 30 to 60 is likewise very striking, for of all the causes of death among males about one twentieth, 4.9 per cent, resulted from suicide, and nearly one eighteenth, 6.8 per cent, from accidents. The percentage for such causes among women is somewhat smaller.

The official statistics show that after the close of the sixtieth year of life a frequent cause of death is old age. It is given for more than one third, 36.4 per cent of all women who died and for more than three tenths, 30.4 per cent of all men. There was apparently no disease or injury in these cases, but a wearing out of the organs of the body.

"If we leave aside," continues Dr. Rahts, "those who died apparently of old age, that is, take into consideration after the close of the sixtieth year only those who died from a more definitely designated disease or injury, we find that nearly one fourth of these died from some disease of the circulatory system, that is, from a disease of the arteries or heart, and probably the cause of death reported for the persons entered in this column of the tables has been largely a hardening of the arteries (arteriosclerosis). Further, fully the eighth of those not dying from old age succumbed to cancer or to the consequences of some other new growth, namely, 13.55 per cent of all such females and 12.12 per cent of all such males. Outside these diseases life at this advanced age is mainly threatened by cerebral apoplexy, pneumonia, or other disease of the respiratory system, as asthma or bronchial catarrh. In this period tuberculosis is apparently by far not so common a cause of death as pneumonia. Suicide, accident, or influenza are about equal as causes of death, namely for about 1 in every 50 males who died excluding those who died of old age. On the other hand, among elderly females suicide or fatal cases of accident causing death were noticeably less frequent than influenza."

There seems to be some danger for women in Germany of dying in childbed. During the decade 1893-1910 for every 10,000 living or stillborn children 36 women died in childbed, of whom about 16 died of puerperal fever, and about 20 of other results of confinement. Several diseases which are greatly dreaded elsewhere and which are easily conveyed, as small-pox, typhus, and leprosy caused but few deaths in the empire during the decade 1892-1902, as did also certain animal diseases to which human beings are susceptible, namely, hydrophobia, glanders, anthrax, and trichinosis. All these diseases just mentioned taken together caused the death in Germany annually of 2.8 persons in every million inhabitants, so that the danger from them in this country is very slight.

Artificial Production of Vigorous Trees*

Valuable Sports and Hybrids That Have An Interesting History

IN an article on the artificial production of vigorous trees, contributed to the Journal of the Department of Agriculture and Technical Instruction in Ireland (No. 1, October, 1914) Prof. Augustine Henry discusses the nature of species, varieties, races, sports, and hybrids, as they appear to be from his researches. Natural species, in the case of trees, are readily recognized by the occurrence of each in a definite region or habitat. We have thus one species of silver fir in Central Europe, another in Algeria, a third in Southern Spain, etc. Of our common trees—oak, birch, and elm—there are pairs of species in the same region, each, however, occupying a different habitat, one species adapted to a dry situation, the other suited to a moister soil. The pedunculate oak is a native of valleys and alluvial flats. It is not protected against evaporation of water, the supply of which in the ground it prefers being always ample. The sessile oak is a native of hilly and rocky districts, where water is not abundant in the soil. Its leaves are covered beneath with hairs, which guard against excessive loss of water by transpiration in windy weather. Similarly two alders exist on the Continent, but only one species, *Alnus glutinosa*, reached our islands, after the retreat of the ice sheet, and before the land connection with France was severed by the formation of the Straits of Dover. The other species, *A. incana*, grey alder, is absent from our native flora, but when introduced is very hardy, and is useful for planting in low lying situations liable to spring frosts. The ash requires such special conditions of soil, that only one species exists in Northern and Central Europe, there being no suitable soil for a second species to inhabit.

A natural species is often a set of individuals uniform over a large area; but it may consist of two or more "geographical varieties," which correspond with distinct territories, each marked by slight differences of foliage, etc., that render the variety better fitted for its own habitat. Thus the Corsican and Austrian pines are closely related, but the latter keeps its leaves two years longer on the branches, so that the dense shade of its abundant foliage preserves moisture in the crevices of the hot limestone rocks, on which it grows in its Austrian and Servian home. The Corsican pine, with half the foliage of the other tree, thrives on granite soil in the moist insular climate of the mountains of Corsica. These two pines only notably distinct in one character, the amount of their foliage—are usually regarded as two geographical varieties of the same species, *Pinus Laricio*, but by some botanists are considered to be two distinct species.

In a species apparently uniform over a large area there may exist varieties, characterized by minute and scarcely describable differences. This is exemplified by the Scots pine. Plots of its seedlings, raised from seed of trees in the forests of Scotland, Russia, Switzerland, etc., differ in vigor and in other respects (immunity to certain fungi, etc.), when all are grown together under identical conditions. Such varieties, with slight differences of structure, may be called races, and are of great practical importance in forestry. Only seeds of the best race, that is, from vigorous trees of the most suitable locality, should be used.

A sport is usually a solitary phenomenon, arising either as a sporadic peculiar seedling from a seed, or developing out of a bud on a tree as a single branch with some peculiarity of twig or leaf. A sport may be looked upon as a freak, not forming the starting point of a new species, but speedily becoming extinct if left to nature. Sports, when of interest on account of the curiosity or the beauty of their appearance, are propagated usually by grafts, cuttings, or layers; being only in rare cases perpetuated by seed. Some sports are due to arrested development. The tree, in the course of its life, often passes through stages, like those of an insect. The seedling of many species differs from the adult tree as a larva from a butterfly. The infant ash has simple leaves. The sport known as the simple-leaf ash is simply a seedling ash, which has never progressed to maturity and may be called a persistent larval form.

Abnormal coloring of leaves, so-called variegation, is a sport, usually starting as a solitary branch on an otherwise normal tree, which, when noticed, is propagated by grafting. Deeply-lobed, crumpled, pitcher-like, and other abnormal leaves occur in many species, and are propagated as curiosities. In sports, reversion is often seen; thus on a fern-leaf beech one or two branches with normal leaves are not uncommon. This reversion may be due to the influence of the stock, as these sports are usually grafted; or it may be explained as the triumph locally of normal over abnormal factors. Such reversions are never seen in hybrid trees. The occurrence of a sport seems to predispose to further sporting; a tree with leaves abnormal in shape will sometimes take on, in one branch, abnormal color as well. These double sports are common in the holly.

Hybrids are combinations of two species or of two varieties, which arise either in the wild state or in cultivation. They are met with in nature as rare individuals on the boundary line between the area occupied by two species. This is well seen in Yorkshire, where a hybrid oak is found in the localities in which the sessile oak of the hills comes in contact with the pendunculate oak of the valleys. Hybrids arise frequently in nurseries, gardens, and parks, where several species are cultivated together.

Hybrid trees are more common than has been supposed. Many valuable trees, the real history of which has not been suspected by botanists, are of hybrid origin. As an example, may be mentioned the fine elm, which is universally planted in Holland and Belgium, where it is known as *orme gras* or *Ulmus latifolia*, Poederlé. This is not, as sometimes imagined, a natural species peculiar to those countries. It is unquestionably a hybrid, which is invariably propagated by layers, all the individual trees on this account being uniform in appearance. It seems to have originated three or four centuries ago, probably as a single seedling, which has given rise by vegetative reproduction since to millions of descendants.

The distinction between sports and hybrids is well known in the numerous so-called "varieties" of the holly. Some are sports of *Ilex Aquifolium*, our native holly; others are hybrids, one parent being the common holly, while the other is either *Ilex Perado*, which was introduced from Madeira in 1760, or *Ilex Balearica*, the holly of the Balearic Isles, which was cultivated at Versailles in 1789. Miller, in his account of the hollies in 1750, was acquainted only with the sports, which had arisen from the common holly, as the other species had not been introduced at that time and hybridization was impossible. The hybrids originated soon after 1800, the earliest apparently being *Ilex Hodginsi* and *Ilex Hendersoni*, which were found by Hodgins as seedlings in his nursery at Dunganstown, Wicklow. Here *Ilex Perado* was cultivated; and old specimens producing flowers and fruit freely are still common in Wicklow gardens. The holly hybrids are vigorous trees, bearing large leaves intermediate between the parent species. The sports of the common holly are always grafted, and are feeble in growth, with a tendency for single branches to revert occasionally to the normal form.

With regard to hybrids, Prof. Henry, by historical research and experiment, has established the fact that many fast-growing trees in cultivation as the Lucombe oak, common lime, cricket bat willow, black Italian poplar, etc., are hybrids. By artificial pollination he has succeeded in raising new hybrids, which display the extraordinary vigor characteristic of the first generation cross; and in his paper gives an account of these. The most notable so far are a hybrid poplar (*Populus generosa*) and crosses between the common ash and American species of Fraxinus.

Advantages of Surface Combustion

AN English firm introduced the Bowe system of surface combustion with liquid or solid fuels for which decided advantages are claimed. Among the special applications illustrated by the booklet are those to enameling, forging, annealing, bolt-making, glass-working, and metal-melting. It is stated that until recently it has been necessary in the enameling industries to employ muffle furnaces in the heating of the ware, for if the combustion gases gain access to it the lead oxide in the enamel is reduced and the work ruined. This effect is due to the incomplete combustion of the gases. As the result of a special test carried out by representatives of an important manufacturing firm, it appears that the combustion products of the new system do not impair the enameled surface, and, therefore, may be allowed to have free access to it, so dispensing with the necessity of muffles, and effecting a great saving in fuel. The advantages claimed for the system generally are: (1) The combustion is greatly accelerated by the incandescent surface, and, if so desired, may be concentrated just where the heat is required; (2) the combustion is perfect with a minimum excess of air; (3) the attainment of very high temperatures is possible without the aid of elaborate "regenerative" devices; (4) owing to the large amount of radiant heat developed, transmission of heat from the seat of combustion to the object to be heated is very rapid.

Electro-Culture of the Soil

A Discussion of the Part Taken by Electrical Processes in Biological Reaction

During the past few years there has been much speculation as to the effects of electricity upon the development of plants and various experiments have been made in the stimulation of germination or growth by electricity, either by the use of electric lights or by the transmission of currents of electricity to the plants or the earth. Results have varied, some investigators claiming great successes, while others express doubts as to the practical value of such methods, or even assert that crops of different kinds are injured by the use of electricity.

One of the advocates of the benefits of electricity for vegetation is Prof. Dr. W. Löb of Berlin, who read an interesting paper on the question at the session in Leipzig in May, 1914, of the German Bunsen Association for Applied Chemistry. Acknowledging that the problem was still unsolved, but claiming that the effort in any direction to settle it was of value, he reminded his hearers that under natural conditions vegetable life exists in the conductive surface of the earth and has above it the dielectric atmosphere. As electrical processes resulting from these conditions, there may be an electrolysis within the earth which produces a directed transmission of ions and a discharge of ions at the electrodes, or by cataphoresis the relations of the colloid substances of the earth or of the parts of the plants are shifted. There can, further, be a fall of potential in the layer of air surrounding the plants, followed by the seeking of equalization through the dielectric atmosphere with the ground or the surfaces of the plants. This latter form of influence is the one best suited for imitation in practical electro-culture, in which there is generally an insulated metal frame or an insulated metal lattice-work stretched parallel to the ground at a certain height above it and equipped with high voltage electricity, which is equalized with the ground by constant discharge.

The natural form of electrical energy to which this practical method bears the closest resemblance, that of silent discharge, opens up the question of the reactions attainable through the equalization of differences of potential by means of a dielectric, a question which extends far beyond the problem of electro-culture. For, as it is certain that the differences of potential necessary for the discharge exist in nature without the aid of artificial devices, they must co-operate in proportion to their chemical activity in the natural reactions. In regard to atmospheric electricity, Berthelot proved that differences of potential, which vary from 7 volts per mèter in dry weather to 500 volts in damp weather, appear between layers of air, between air-surfaces and leaf-surfaces, or between the air and the ground. The equalization of these differences generally occurs in the form of dark discharges. Another form of continuous discharge at the earth's surface is the glow discharge. The part taken by sunbeams in generating the surfaces of potential-levels has been investigated of late years by Noden, and in the sunbeam, we should remember, besides the heat and light rays, ultra-violet rays are also active, the importance of which for ionizing in gases, or in the generation of electrons, is known.

All this led Dr. Löb, who had spent many years in investigating the chemical effects of the silent discharge to take up the problem of electro-culture in connection with the silent discharge and to make experiments to determine the part taken by the electrical processes in the chief biological reactions. In his address, which is given in the German journal *Zeitschrift für Elektrochemie*, he says:

"In order, first of all, to gain a general position to this problem, it is only necessary to recall that undoubtedly during the process of equalization of the differences of potential in the dielectric, if the dielectric is moist air, definite reactions are regularly caused, as, for instance, the formation of ozone, peroxide of hydrogen, and oxide of nitrogen. The further question naturally arises, whether these substances influence the vegetative processes, as the assimilation of carbonic acid and nitrogen, or processes of oxidation, whether they accelerate or retard the numerous enzyme reactions. It is also known that chemical reactions are not merely limited to the domain of gases, but that the interface between the ground and the air also causes reactions which directly affect the substances within the ground. Thus, Berthelot proved that a number of fixed bodies and fluid substances absorb nitrogen. If the ultra-violet rays are also taken into consideration, the number of possible reactions is much larger. Recently Neuberg, among others, showed how easily and completely many biologically important substances are changed by the ultra-violet ray."

These conditions and results lead to the deduction that electrical energy is of much importance in the reactions of life. The silent discharge seems to be especially suited for use in investigating such reactions because in it, under exclusion of higher temperatures, electrical energy appears united with the ultra-violet ray, as has been shown by Warburg, and because relatively strong chemical effects are produced.

Among the biologically important investigations undertaken by Dr. Löb are: "1. The assimilation of carbonic acid from moist carbonic acid over formaldehyde up to glycolaldehyde; 2, the synthesis of the fatty acids connected with the assimilation of carbonic acid; 3, the synthesis of glycocol from carbonic acid, water, and ammonia over the intermediate stage of the formamides, a reaction which may be regarded as the first phase of the assimilation of nitrogen in the process of the formation of albumen; 4, the hydrolysis of starch; 5, the removal of the amino group from glycocol."

When these results are compared with the reactions which can be produced in the atmosphere, as the formation of ozone, peroxide of hydrogen, and oxide of nitrogen, the reactions attainable by the action of the silent discharge may, according to Dr. Löb, be summed up as follows: "*a*, Direct syntheses or decompositions are produced from the substances of the atmosphere or of the conducting electrode (fluid or surface of the earth); *b*, substances are produced which either retard or accelerate other biological processes; *c*, reactions, the course of which only affect themselves, are accelerated or retarded directly by the influence of the electrical discharge, that is, without catalytic agents."

In company with Dr. A. Sato, Dr Löb, about a year ago, took up the question whether the enzyme reactions, so important for the germinating plant, are modified in their course by the influence of the electrical discharge. To settle this point it was necessary to determine: the condition of the substrata under the influence of the discharge, whether the enzymes are affected by the discharge, and in what way the discharge acts upon the enzymatic modification of the substratum. The experiments had to be made both with atmospheric air, and under its exclusion in order to avoid the appearance of ozone, hydrogen peroxide and oxide of nitrogen, and involved tedious and delicate experiments.

As the experiments sought only to determine the main conditions, animal not vegetable enzymes, were used, solutions of suitable dilution being made from the dried substance of the pancreas of hogs. The results showed that the enzymes and substrata used were matters of importance, so that there is a possibility that the action of the discharge upon the vegetable enzymes might be different from its action upon the animal enzymes. Among the most important enzymatic processes of the germinating plant are the diastatic, tryptic, and lipolytic reactions of the enzymes. In his summary of results Dr. Löb says

"1. Watery solutions of starch are hydrolyzed under the influence of the silent discharge and the glow discharge in the presence of oxygen and under its exclusion. At the same time the part of the starch not hydrolyzed is altered in another way, perhaps in the direction of a polymerization, so that the part of the starch exposed to the discharge but not hydrolyzed has more power of resistance to diastase than starch not treated by electricity. 2. The diastatic properties of the pancreatic solutions are decidedly retarded by the electrical treatment. 3. The reaction between diastase and starch is retarded by the electrical treatment. 4. Peptonized silk (partially hydrolyzed silk) solutions are hydrolysed only slightly by the discharge, whereby a little free ammonia appears. The amount of the amino acids and of the non-colloidal nitrogenous substances are not demonstrably increased. 5. The tryptic properties are retarded by the discharge. 6. In the presence of peptonized silk the tryptic properties are not demonstrably injured through the peptone. 7. In the presence of fibrine the electrical treatment increases the tryptic properties which act upon this, the digestion of fibrine is accelerated."

It was, curiously, found that in some cases the discharge injured the enzyme when the latter was exposed to it without a substratum, while when the substratum was present the action of the enzyme was accelerated. The reason for this may be that the discharge changes the colloid condition of the enzyme and encourages flocculence. If this process begins without a substratum it is possible that the adhesion of the enzyme to the substratum is made more difficult should the latter be added later. If the substratum is present during the development of flocculence, the chemical affinities undoubtedly existent between it and its enzyme may influence the adsorption process between the two in the same direction, thus accelerating the enzyme reaction.

Another fact gained from the experiments is that the nature of the substratum is of importance for the effect of the discharge, which would imply that the sensitiveness of the specific character of the enzymes varies as regards electrical treatment. The reactions of vegetative life, assimilation of carbonic acid and nitrogen, process of oxidation and reduction, enzymatic decompositions of highly molecular substances, which frequently precede further transformations, as well as the numerous processes of polymerization and syntheses of other kinds, are all closely connected with the form of the supply of energy. Numerous questions arise as to the action of the sun's rays on the growth of plants and the connection of light and heat with electrical energy. These questions will have to be experimentally answered before the scientific basis of electro-culture can be laid.

In the discussion which followed the reading of the paper before the association at Leipzig some doubt was uttered as to the actual results of electro-culture, the opinion being expressed that the effects of electricity seem either negative or secondary. The necessity was also dwelt on for extreme caution in all such experiments, as ferment infections caused by ordinary microorganisms could lead to mistaken deductions. F. Haber of the Kaiser Wilhelm Institute, at Berlin, gave the results of his investigation with others of the assimilation of a leaf of cherry laurel in air filled with carbonic acid. It was found that the electric field produced no change in the assimilation unless a glow discharge was obtained. Both continuous and alternating currents were used, also an alternating field was tried. The reaction produced by the glow discharge injured assimilation. The admixture of ozone or oxide of nitrogen with the air had the same effect as the glow discharge. The concentration was diluted until no injurious effects were perceptible, but no useful results were attained. In conjunction with these experiments, Messrs. Knight and Priestley of the Botanical Garden of the University, of Leeds investigated the breathing of plants under the influence of electric fields and reached only negative results. These and the investigations of other scientists mentioned led him to the opinion that when success is obtained in electro-culture the question proves to be not that of electrical action upon one of the physiological functions of the plans, but merely that of an entirely secondary effect of electricity.

In reply to the inquiry how he supposed the glow discharge affected enzyme action, whether it was through the production of certain chemical substances which influenced this action, Dr. Löb said that any influence could only be on the surface, as the enzyme solution forms an electrode within which hardly any perceptible fall of potential could take place. The entire fall of potential occurs in the atmosphere; the reaction takes place on the surface of the fluid. Perhaps the best way to describe how the chemical action arises would be to compare the phenomena with the action of the ultra-violet ray. If ultra-violet rays are thrown on a sterilized solution of sugar the solution at once changes, it absorbs oxygen, oxidizing processes appear, etc. With the aid of the theory of electrons, various schemes could be advanced as to how this happens, but he did not wish to form a definite theory until more facts had been determined. C. Schall of Leipzig spoke of an experiment once made with an electrically charged metal in a solution with which it acted when not charged. It was claimed that the resulting yield was greater, so that perhaps the reaction was accelerated in some manner. It was also supposable that leaves charged at a fairly high potential, 100 volts, could, when the constituents there combined, act upon the speed with which a reaction takes place on the surface.

In reply to an inquiry as to how the experiments were made, Dr. Löb said the enzyme solutions were exposed to the discharge in suitable vessels, and simultaneously the same solution was set in a similar vessel without exposure to discharge. Then the enzyme strength of these enzyme solutions was determined, and it was settled whether the speed of the enzyme reaction had been increased or retarded in the hydrolysis of starch or in the digestion of peptone, casein, or fibrine. Next the behavior of the substratum without the enzyme under the influence of the discharge was investigated, and after all this the enzyme reaction on the substratum was allowed to go on to completion simultaneously under the effect of a discharge and without discharge. The result was quantitatively determined.

Records of Radio Time Signals*

Made With a Physiological Recorder

By Prof. C. W. Waggoner, West Virginia University

From the date of Galvani's historic experiment with the frog muscle in 1786 to the present, physiologists have investigated the effect of electrical and mechanical stimulus upon this remarkably sensitive physiological mechanism. Helmholtz is credited with having made the first careful study of the muscle-nerve preparations in 1852 and the use of these preparations from the frog for the study of the characteristics of these tissues is common in all physiological laboratories.

This paper is a report on some records made with the muscle-nerve preparations of a frog of the radio time signals sent from the Government naval station at Arlington, Va., and received on a small aerial erected on the campus of the West Virginia University.

Dr. Lefeuvre[†] of the University of Rennes, France,

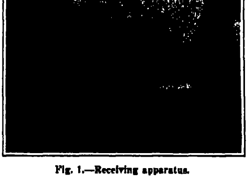

Fig. 1.—Receiving apparatus.

succeeded in obtaining some records of the wireless signals sent from the Eiffel Tower, Paris, by using the muscle-nerve preparation of a frog, transmission of such signals from Paris to Rennes being for the most part over very level land, and at a distance of approximately two hundred miles. He used a sensitive electrolytic receiver, shunting the recorder current around the high resistance telephones which were placed in series with the detector and potentiometer.

The distance from Morgantown to Arlington, Va., is approximately 182 miles and in between lie three big mountain ranges, one ridge of which rises 2,200 feet above the level of the campus. The aerial used in these experiments consisted of four cables of stranded copper wire, seven strands of No. 21 wire to each cable. The aerial is of the inverted L type, the highest point being 112 feet above the ground, and has sufficient length to give it a natural wave-length of 375 meters.

In Fig. 1, showing the receiving apparatus, *A* is an induction type receiving transformer which was constructed in our shop, and has a tuning range of 50 to 4,000 meters with a comparatively short aerial. *C* is a variable condenser of approximately 0.001 microfarad capacity. *W* is a buzzer-driven wave-meter, the inductance of which is loosely coupled with one turn of the aerial lead-in. The electrical connections are those commonly used for receiving long wave-lengths. The secondary of the receiving transformer is shunted by the variable condenser to insure ease in sharp tuning; around the secondary is also shunted a circuit containing the detector and a small fixed condenser in series. The terminals leading to the recorder are connected to a switch so that either the recorder leads or the telephones may be shunted across the small fixed condenser. The buzzer used to excite the wave-meter is of the type described by Austin.[1] The buzzer is very simple to construct and gives such a steady, high pitched note in the telephones that we have found it a very valuable addition to the general equipment of the laboratory. The buzzer shown in the figure will operate on two dry cells for six to eight hours at a time without requiring any adjustments or attention. Such a buzzer is essential to the most careful adjustments on the silicon detectors. The detectors are shown in the figure at *D* and are mounted upon a spring support. Simple silicon-steel detectors without batteries were used throughout these experiments, and it was found that they were amply sensitive for the recorder. The spring support for the detectors was found to be a great convenience. Those who have used this type of detector know how sensitive it is to a slight jar, and with this type of support there was no difficulty keeping several detectors in adjustment for weeks at a time without disturbing them in the least. The experiments were made during February and March of last year, and little trouble was experienced from static discharges in the atmosphere.

The mechanism for making the records is shown in Fig. 2. The frog is shown at *F* (the table upon which it was mounted was tilted to the vertical position for the photograph). The preparation was made by removing the frog's brain, destroying the spinal column and dissecting out the sciatic nerve which energizes the gastrocnemius muscle. The muscle was cut free at the lowest point and fastened by a cord to one end of the long lever shown at *L*. This lever, with a suitable sharp marker on its end, was arranged to move, at the contractions of the muscle, over a smoked paper kymograph *K* driven by a constant speed motor *M*. At *T* is shown a small Zimmermann time-marker which was adjusted to record seconds simultaneously with the record made by the muscle-nerve preparation. This time-marker has a fine Swiss watch movement, and a comparison of its record with the standard time record made by the muscle will show an error too small to be determined on the scale drawn on the record.

The method of making a record was to tune the receiving transformer with the aid of the wave-meter to 2,500 meters; then as soon as the signals began to arrive the telephone leads were replaced by the leads to the recorder, and the two platinum points or electrodes in contact with the nerve were moved along the nerve until a strong but regular response to the signals was obtained. The records were fixed by coating them with a thin solution of shellac in alcohol.

With a satisfactory preparation no difficulty was met with in getting full five-minute records of the time signals both at 12 noon and 10 P. M. (eastern time), often the same preparation serving to make records at both these hours. In a number of cases it was found that when a frog was prepared only a few minutes before making the record it was entirely too sensitive, and a complete tetanus would result from the stimulus of the first few signals, and no results could be obtained. After twelve or fourteen hours this same preparation would often give an excellent record. A few frogs were found whose muscle-nerve preparations failed to respond at all. This failure may be due to the fact that only winter frogs were to be had and at this time in their hibernation their vitality was probably very low.

Figs. 3 and 4 show some records made by this type of recorder. Fig. 3 shows a record made by a freshly prepared specimen. This record was taken at 10 P. M. and on record following the time dash at 10 will be found t weather signals. The muscle-nerve preparations will not respond to rapidly repeated stimuli, especially if the muscle is fatigued, as was the case in the record shown in Fig. 3, and it is of course impossible to interpret the weather signals from this record. It

Fig. 2.—Recording apparatus.

was possible often to record the operator's signature at the close of the last time dash, but only when the frog was used in making signals for two or three minutes. Fig. 4 is a record showing extreme fatigue of the muscle. This record was made by a muscle-nerve preparation which had been prepared twenty-five hours before this record was made and the rapidly decreasing amplitude of the vibration indicates the fatigue.

From the experiments performed it seems that this type of recorder, while remarkably sensitive to small electrical impulses, is limited to slowly applied signals if the record is to be taken for any considerable length of time. A freshly prepared specimen will show complete tetanus if the impulses occur as rapid as twenty-five or thirty times a second. We were unable to get any very satisfactory records of the weather signals, except to record some of the numerals which consist of well spaced dots and long dashes, even with a freshly prepared specimen.

Like all recorders, this one responds to static discharges, and if the static current is very strong the high current tends to cause tetanus and ruin the record. It is possible that this type of recorder could be used by observatories in connection with the chronograph for finding the rate of clocks, making use of some sort of an amplifier, such as the Audion, in such stations so far distant from the sending station that the received current on the antenna would not be sufficient to operate the muscle-nerve preparation. The response to the signals is very rapid. Physiologists have found that this muscle-nerve preparation will respond to the stimulus in one-one hundredths of a second after the current has reached the nerve.

Hydrogen, Its Technical Production and Uses*

By A. F. Seeker

IN recent years the cheap production of hydrogen on a large scale for technical purposes has become a problem of some importance. Formerly it was used occasionally for filling balloons and in the oxy-hydrogen flames of the so-called "calcium light." Being the lightest of the common gases and of a correspondingly high sustaining power, it has become essential for the filling of dirigible balloons with their heavy burden of propelling machinery. Such uses, however, have become of rather secondary importance, and it will probably be only a short time before the dirigible balloon and the "calcium light" will have been permanently discarded in favor of heavier than air machines and varied forms of projected lights operated by electricity.

The oxy-hydrogen flame is now becoming a common tool in the hands of the artisan in working refractory metals; liquid oils and soft greases are now "hydrogenated" to produce acceptable lard and butter substitutes, and also solid fat suitable for the manufacture of hard soaps; and lastly, the use which promises to consume enormous quantities, ammonia is manufactured from hydrogen and atmospheric nitrogen. All these uses tend to make the problem of the production of cheap hydrogen one of considerable importance.

The employment of the oxy-hydrogen torch is too well known to require description here. The commercial "hydrogenation" of oils and fats is of recent introduction. The process consists in treating the oil or grease in a suitable vessel containing a catalyzing agent, generally nickel, with hydrogen under pressure. The oil is violently agitated in order to bring it into intimate contact with the hydrogen and catalyzer. The result is that the glycerol esters of the unsaturated fatty acids, which generally consist for the most part of oleic acid, become saturated, and the mono-, di-, or triolein, as the case may be, is converted into the corresponding stearin. The oleins are either liquid or semi-solid at ordinary temperature, and pr[oduc]e soft soap or soap that will not hold much wate[r] without becoming soft. The stearins are solid fats at ordinary temperatures and produce hard soaps. Thus by the process of hydrogenation, cotton seed and corn oils are to-day being converted into lard and butter substitutes, and the soft waste grease which formerly could only be used sparingly in soap on account of their softening effect can now be employed alone as soap stock. The importance of this is understood when the soaring prices of animal tallows are taken into consideration.

In view of the impending exhaustion of the Chile nitre beds, the problem of the fixation of atmospheric nitrogen for the manufacture of artificial fertilizers has received constantly increased attention. Electrical methods for the production of cyanamid from calcium carbide and nitrogen, and the flaming arc process for making nitric acid directly from the air have been established upon a successful commercial footing, but these require such an enormous expenditure of energy that they can only be operated profitably where there is an abundance of cheap water-power. If only these processes were available, countries lacking in water-power would be placed at a distinct disadvantage, and for this reason many chemists, particularly those of Germany, have labored to find a process better suited to the conditions surrounding them. The details of this search were described in a most interesting manner before the Eighth International Congress of Applied Chemistry, by Hofrat Dr. H. A. Bernthsen, who is the Chemical Director of the Badische Anilin und Soda Fabrik, the owners of a synthetic ammonia factory now in successful operation at Oppau.

* The Chemical Engineer.

The process, which has been named after Haber, its inventor, consists in passing a mixture of pure nitrogen and hydrogen under a pressure of 150 to 250 atmospheres through a tube filled with a catalyzer and heated to 650 deg. to 700 deg. Cent. The hot gases then pass through a heat regenerator and thence through an ammonia absorber, after which they are replenished with fresh gas mixture and forced by a pump back over the outer walls of the contact tube and then through the contact mass to repeat the circulatory course already described. Only a part of the gas mixture is converted into ammonia by a single passage through the converter, but the gases are made to circulate continuously through the apparatus, the ammonia being absorbed each time as the mixture issues from the heat regenerator at the end of the contact tube. The gases are replenished with fresh hydrogen-nitrogen mixture as required. The contact mass consists of pure iron containing small amounts of certain so-called promoters which may consist of oxides, hydroxides, or salts of the alkalies or of the alkaline earths, and also many other substances of the most varied nature, especially metallic compounds or the metals themselves.

There have been many ways proposed for the producing of hydrogen on a large scale, the most important of which are the electrolytic and the water gas process. The studies of A. Wegener and others lead to the belief that at an altitude of about 75 miles the atmosphere consists of pure hydrogen and nitrogen that would be ideal for the Haber process. Unfortunately no means of piping these gases down to our sphere of action are known and we must content ourselves with more laborious methods of production.

At European army posts, hydrogen for military balloons is commonly generated from scrap iron and sulphuric acid, the reaction being accelerated by heating the mixture to about 55 deg. Cent. For field operations zinc is used in place of iron and the generators are mounted on wheels to facilitate transportation. Three other, and more modern means, of generating hydrogen are used for field purposes and will no doubt be adapted for other than military uses in places difficult of access where the gas is needed. These processes were invented by G. F. Jaubert, a Frenchman, and were named by him respectively, the "Hydrolith," "Silicol" and "Hydrogenite" processes.

Hydrolith is formed by heating metallic calcium in an atmosphere of hydrogen, producing a hydride, CaH_2, which when treated with water reacts as follows:

$$CaH_2 + H_2O = Ca(OH)_2 + 2H_2$$

Just as calcium carbide generates acetylene. Hydrolith is a white crystalline powder, decomposing at 600 degrees in a vacuum, and usually contains about 90 per cent of CaH_2, the rest being nitride and oxide. One kilogram yields about one cubic meter of hydrogen. The apparatus designed for using hydrolith in the French army is very ingenious, can readily be transported and has a capacity of 1,200 cubic meters per hour. An army dirigible can be filled in four hours. The high cost of hydrolith, $1.33 per kilogramme, will at present seriously restrict its use outside of military operations.

The Silicol process consists in treating powdered ferrosilicon, or mangano-silicon with water and caustic soda. It does not appear to have gained extended use because of the more troublesome manipulations and the greater difficulty of controlling the evolution of gas as compared with the other methods.

Hydrogenite is composed of ferrosilicon (containing 90 to 95 per cent of metallic silicon) 25 parts, caustic soda 60 parts and dry slaked lime 20 parts. The ingredients are reduced to a very fine powder, intimately mixed, and pressed into brick weighing 25 to 50 kilogrammes. Being very hygroscopic, each brick must be sealed in a tin box to prevent decomposition. In generating hydrogen the brick is placed in a metal chamber having double walls, the space between the two walls being filled with water. Vents are placed in the upper part of the inner wall leading to the central chamber containing the hydrogenite so that the steam formed during the combustion may gain access to the charge and increase the yield. The cover of the tin containing the hydrogenite is opened, the tightly fitting lid of the generator fastened in place and through a small hole in the latter a red hot wire is thrust into the charge. The mass burns quickly, without flame, generating heat and evolving hydrogen according to the equation:

$$Si + Ca(OH)_2 + 2NaOH = Na_2SiO_3 + CaO + 2H_2$$

One volume of the compressed hydrogenite yields 800 volumes, or 270 to 370 liters per kilogramme, of pure hydrogen, at a cost of about 32 cents per cubic meter. The requisite apparatus for field purposes weighs about 900 kilogrammes.

The methods employed upon a large scale are, of course, capable of producing the gas much more cheaply. In one of these an iron, clay lined retort is filled seven-eighths full of coke, ignited and raised to a white heat by an air-blast. The retort is then closed and a cheap hydrocarbon like crude petroleum or coal tar is injected into it from the top for about 20 minutes or until the temperature has fallen below the proper cracking point, the gas thus generated passing through a sprinkling tower and filtered into the gasometer. The oil injector is then shut off, the retort opened, the air blast again turned on, and the process repeated indefinitely with periodical renewal of the coke and removal of the ashes. The product contains about 2.7 per cent CO, 96.0 per cent H, and 1.3 per cent N, and has a specific gravity of 0.1. The gas can be still further purified to a content of 98.4 per cent H, by passing it through suitable absorbents, and is produced at a total cost of 3 to 4 cents per cubic meter, according to the size of the plant and the materials used.

Large amounts of hydrogen are obtained as a by-product in the electrolysis of salt solutions in the manufacture of chlorine and of caustic soda. The electrolysis is effected in a cell having a cement diaphragm which is not attacked by chlorine or caustic soda. The electrodes are iron and carbon, the latter being used as an anode. The reaction which is as follows:

$$2NaCl + 2H_2 = 2NaOH + Cl_2 + H_2$$

yields 7,000 cubic feet of hydrogen for every ton of salt. A cell operates on 15,000 horse-power at Griesheim, Germany, producing 215 million cubic feet of hydrogen per annum.

Two other methods, now little used, consist, (1) in passing superheated steam over red hot iron, and (2) in conducting water gas through suitable absorbents so that the carbon-monoxide and hydro-carbons are removed, leaving behind the hydrogen and nitrogen. A third process which is increasing in application was devised by Linde, Frank and Caro. In this, water gas which consists mainly of carbon monoxide and hydrogen is compressed and cooled to the liquefying point of the carbon monoxide. Upon relieving the pressure the mixture expands and in so doing is cooled still further so that the carbon monoxide and most of the impurities separate out in liquid form, allowing the hydrogen to pass off in a fairly clean (97 to 98 per cent H) condition. The mixture containing the liquid carbon monoxide is later vaporized and used in combustion motors for power.

The growing demand for cheap hydrogen for industrial uses will act to promote improvements in both the electrolytic and the water gas processes because both require comparatively cheap raw material.

Electric Waves and Oscillations

A Means of Investigating the Interior of the Earth

By Dr. Gotthelf Leimbach

The attempts which have, until very recently, been unsuccessful to utilize electric currents and waves in the investigation of the interior of the earth extend back, respectively, to the years 1830 and 1901. The first practical results in this field, attained by Heinrich Löwy and myself in 1910 and 1911, attracted by no means the attention in mining circles that we had anticipated. Even at the present day, in the face of a great number of successful achievements, many persons are still skeptical about the development of electrodynamic methods of exploring the earth. Judging from my experience, this is due especially to the fact that neither the physical basis nor the scope of the various processes in question are correctly understood. Wireless telegraphy, the most familiar application of electric waves and oscillations, is commonly accounted one of the marvels of modern times; while the application of the same phenomena to subterranean exploration is consigned to the realm of fable. In the following remarks I hope I may be able to convince the reader that the latter application is neither impossible nor incomprehensible.

The physical principles involved in this subject were discussed in detail in the journal *Kali*, volume 7, 1913, No. 17. I there explained the principles of the wireless transmission of electrical energy through space, in order to save practical mining men the necessity of consulting a work on wireless telegraphy. Hence, I shall in the present article limit myself to a short sketch of the various processes.

The possibility of applying electrical waves and oscillations in the investigation of the earth's interior depends upon certain physical differences in the materials constituting the earth's crust. The latter fall into two classes, according as they conduct electrical currents, or, on account of their slight conductivity, are classed as insulators. Good conductors of an electrical current are impervious to electrical waves, whereas the latter pass almost unaffected through insulators.

As electrical waves differ from light waves only in wave-length, optical phenomena may be directly reproduced by the former. With an apparatus for emitting waves (a sender) and one for recording them (a receiver), we may make qualitative observations on the material lying between the two instruments. As stated above, materials that are conductive to an electrical current will not permit the passage of the waves. Among the conductors are water,[1] salt solutions, and strata saturated with these; also a large number of ores.

I. INVESTIGATION BY MEANS OF ELECTRICAL WAVES

a. Absorption Method.

A first practical method of investigation, the absorption process, takes the form of testing rocks for the presence of various substances by examining their capacity for admitting the passage of electrical waves. Practical investigations of substances which are opaque to such waves (ore and salt solutions) were made by Dr. Löwy and myself in the state mine of Ronnenberg, near Goslar, and also by Dr. Löwy at Scharley. These confirmed the fact that good conductors of an electrical current are opaque to electrical waves. A fair agreement with the theory, i. e., absence of marked absorption, was yielded by the rocks occurring in potash mines; viz., various salts, anhydrite, clay, etc. Numerous investigations in a large number of mines proved that there could be no doubt about the transparency to electric waves of the rock-forming minerals constituting the earth's crust—the ores excepted—when these substances are *dry*.

b. Reflection Method.

The reflecting power for light-waves of a great number of substances is as accurately known as their various degrees of transparency. Among the excellent reflectors of electrical waves we find, again, the substances that are conductive to an electrical current, viz., metals, ores, salt solutions, and water. With senders and receivers of electrical waves which have their antennae so arranged as to send or receive only in a selected direction it is possible, therefore, to locate these conducting substances through intervening material that is transparent to waves, merely by changing the direction of the antennae. From the angles between the antennae of the sending and receiving instruments, respectively, and the ground when the intensity of the signals received is greatest, the depth of the reflecting layer (ore or water) can be computed. Practical investigations at the swimming hall in Göttingen, and also at Barsinghausen and Scharley, have proved the strong reflecting power of water and ore.

c. Interference Method.

In many cases, e. g., in determining the location of a water-bearing seam in the interior of a mine, it is impossible to use long antennae, movable at will. Such a seam may, however, be located with stationary sender and receiver if the wave-length of the system is so chosen that the waves running directly from the sender to the receiver are neutralized by those reflected from the conductive substance. This will happen when the path of the reflected waves is longer by ½, 1½, 2½, etc., wave-lengths than that of the direct waves. The two trains of waves have a different direction of oscillation, and opposite phase; their effect upon the receiver will be *nil* in case they have equal energy. On the other hand, if the difference between the length of path amounts to one or a number of whole wave-lengths, the waves will then be of the same phase and their effect upon the receiver will be reinforced. As we are able to vary at will the wave-length of a sender and a receiver, we can ascertain by this method, as by the others, the presence and the depth or distance of a conductive reflecting seam. Experiments of this sort on a small scale were made by the writer many years ago in connection with investigations of quite a different character, viz., the study of moist soils, at the geophysical institute of Göttingen University.

d. "Quarter-wave-length" process.

In the method above outlined both a sending and a receiving system are used. About a year ago it occurred to me to ascertain whether the wave emitted by the sender and returning thereto after falling vertically upon a reflecting surface would not affect the oscillations of the sender in a manner analogous to what occurs in the interference method. A method depending upon this principle would have the advantage of great simplicity, as compared with the interference method, because it would eliminate the second receiving system. In the laboratory of the "Erforschung des Erdinnern G. m. b. H." ("Subterranean Investigation Company, Ltd.") at Göttingen, experiments on a small scale gave the surprising result that reflecting surfaces could be located the length of which was less than that of the antenna and the breadth only one hundredth the length of the antenna, or less. This method is, therefore, extremely sensitive. As the sender shows particularly characteristic effects for differences of a quarter of a wave-length or multiples thereof, this process has been called the "quarter-wave-length" method. From the position of the characteristic maxima and minima of the effect of the reflected waves in relation to the wave-length the depth of the reflecting layer may be very accurately determined. This method is appropriate for seeking ore or water from the earth's surface in all cases where the intervening strata do not wholly absorb the waves. An expedition sent out by the company above mentioned, under the auspices of the Imperial Colonial Office and other interested parties, is now engaged in prospecting by this method in Southwest Africa.

II. INVESTIGATION BY MEANS OF ELECTRICAL OSCILLATIONS.

The following methods work with a single system of apparatus and depend upon the influence exerted on the apparatus by its immediate environment. The quarter-wave-length method therefore forms a connecting link between the methods in which the course of electrical waves is followed between two stations and those which involve observations of the influence exerted by the environment upon the oscillations of a single system.

a. Capacity and Damping Method.

The wave-length, λ, of an oscillating system, e. g., of an antenna, is determined by the latter's self-induction, L, and capacity, C, according to the relation $\lambda = 2\pi\sqrt{LC}$. The surroundings of the antenna have no influence on the self-induction, which therefore need not be considered further. On the other hand, the capacity of an antenna is strongly affected when the lines of force running from the positive to the negative end of the antenna pass through some medium other than air. Each substance possesses its own dielectric constant—a number analogous to specific gravity—which shows how many times the capacity of an electrical system is increased when operating in the substance in question instead of in air, the dielectric constant of which is unity.

The use of this principle of various dielectric constants in different substances seems quite pertinent when we learn that water has a constant of 81, while most rocks have constants varying between 4 and 12. We may therefore assume that the presence of a water-bearing seam will make itself felt through an increase in the capacity of the antenna, even at considerable distances. That even the slightest differences in the dielectric constants of various rocks occurring in potash mines cause differences in the capacity of oscillating systems has been determined through the detailed investigations of Dr. Erich Mayer and myself.

A great advantage of this method consists in the fact that substances having different dielectric constants affect not only the wave-length but also the damping of the oscillations in different degrees. In conductive substances energy is used up in the production of vortical currents, and to these substances belong, as we have said, water and salt solutions. Non-conductive substances of high dielectric constant virtually affect only the capacity of the system. Hence, this method should permit not only the discovery of the presence of substances of different dielectric constant, but also at least a qualitative identification. Thus we have the basis of a method which can be applied, first of all, in mining and shaft-sinking, to the task of determining whether there is danger of an irruption of water or salt solutions.

b. Examination of Frozen Shafts.

Water-bearing and unstable soils are now, with increasing success, frozen in connection with shaft-sinking, in order to produce a cylinder of resistant material within which the sinking of the shaft can proceed without danger. That this operation has not always been successful is due to the fact that it has hitherto been difficult to determine whether the frozen layer was sufficiently solid at all points. The efforts to remedy this difficulty have been limited practically to the construction of more or less trustworthy sounding-devices for testing the behavior of the various freezing-pipes. From the behavior of any two successive pipes, and with the aid of the data deduced from past experience, it is decided whether the amount of cold applied is sufficient to freeze the section of ground between the pipes, or whether a supplementary freezing-pipe ought to be installed between them. Moreover, in order to freeze with tolerable certainty any strata containing salt solutions, which have led to many breaks and accidents, very low temperatures are used. In spite of all improvements, the fact remains that there has heretofore been no means of promptly detecting the presence of disturbing factors within the earth. Here again the aid of electrical oscillations may be invoked. Unfrozen water-bearing or solution-bearing seams lose their electrical conductivity in proportion as the water they contain is changed to ice. Hence, the iron freezing-tubes must be used as antennae and made to give rise to electrical oscillations, which will be effected by the immediate environment in the same manner as in the capacity method. Experiments on a small scale confirmed the utility of this process; ice was found to be transparent to electrical waves. The conductivity of water containing a small admixture of salts was reduced to about $\frac{1}{100,000}$ of its original value by cooling from room temperatures to 10 degrees below zero Centigrade.

Meanwhile it remained to be determined whether these assumptions would be as perfectly realized in an actual shaft-freezing operation, with its envelope of frozen soil, as in experiments on a small scale. We had no difficulty in transferring our laboratory experiments to the practical conditions of such an undertaking. My collaborator, Dr. Mayer, and myself were able within a few minutes to excite oscillations of a previously determined wave-length in any freezing-tube we happened to select, at an installation between Rössing and Barnten where the necessary facilities were kindly placed at our disposal by the "Tiefbau- und Kälteindustrie A.-G." of Nordhausen (formerly Gebhardt & Koenig). The last preliminary condition of the proposed method was thus fulfilled; the frozen envelope of the shaft gave an effect exactly analogous to that produced under artificial conditions in the laboratory.

Our request for permission to continue our experiments at the Gilten shaft was cheerfully complied with by the "Deutsche Schachtbau-Aktiengesellschaft" of Nordhausen. With funds raised on the strength of our success at Rössing-Barnten, we only succeeded in test-

* Translated from *Zeitschrift des Vereines deutscher Ingenieure*.

[1] Pure water is a non conductor. The author's statement is, however, true of all water found in nature, this being conductive in virtue of the substances it holds in solution.—Translator's note.

ing the frozen wall of the shaft so far as to discover, at the outset, the presence of an unbroken layer near the surface, which hindered the peneration of the electrical waves to the lower end of the freezing-tubes. This layer, according to our measurements, lay at a depth of barely 2 meters. Subsequent investigation showed that a thin layer of the freezing-mixture lay upon the cement block in which the drive-pipes were installed, and this had not frozen.

Had not the shaft been, for the most part, already lined with iron, we should have been able to apply successfully here a method which we have applied, with good results, in a Hanoverian potash mine, where we had to work through a much more strongly conductive layer than the one above mentioned. However, both here and also a few weeks later in a shaft-freezing installation kindly placed at our disposal at Heerlen, Holland, by the "Deutscher Kaiser" Mining Company, we had to content ourselves with the positive result of having been able to detect not only the presence but also the depth of an unfrozen seam, which lay even deeper at Heerlen than in the case just referred to.

Recognizing the fact that we must, for the future, generally expect such layers of disturbance near the earth's surface, and a more or less extensive iron lining in the shaft, I endeavored to devise another method in which the investigation of the freezing wall of the shaft would be entirely unaffected by such obstacles. The ample equipment of our physical laboratory greatly facilitated this undertaking. Setting out from certain very definite experimental conditions, my colleagues, Drs. Mayer and Kröncke, and myself succeeded in exciting electrical oscillations in two bare wires buried in wet earth—representing a freezing-tube system on a small scale—and in determining the constants which furnish information as to the separation of the tubes and the location of unfrozen places in the frozen wall. After experimenting under a variety of conditions we came to the conclusion that the presence of a conductive layer under the sill of the superstructure, due to the often practically unavoidable spilling of the freezing solution in filling the tubes, and also the existence of an iron lining ("tubbing") in however advanced a stage of construction, need not interfere with the examination of the frozen earth; indeed, the iron lining can be turned to good advantage in connection with this process.

c. Investigations in Connection with the Cementation Process.

The use in shaft-sinking of the cementation process, in which crevasses in the wall of the shaft are closed by forcing cement into them, has steadily gained adherents notwithstanding numerous failures. Unquestionably this process has its advantages in many cases, especially when water needs to be kept out in comparatively small areas at great depths. While in the freezing process it is possible to form a tolerable idea, through various modes of observation, of the successful progress of the work, in the cementation process the measurement of the water flowing into the drill-holes, or of the amount of cement forced out by the water, furnishes the only method of testing the solidification of the dangerous crevassed strata. The strong outward resemblance of the cementation to the freezing process led me to consider the applicability to the former of the electrical method of testing for water. The method used in the freezing process could not be applied without modification, since in this case it was not a question of insulating the drill-holes from water-bearing seams. However, preliminary experiments at Göttingen and also in an actual shaft where cementation was in progress showed that the waves from a highly isolated antenna can penetrate so deep in the earth that from the reaction of the earth upon the antenna it is possible to gain a knowledge of the presence of water in crevassed strata. An advantage offered by the electrical test consists in the fact that the antenna is not essentially affected by thin newly-formed layers which diminish the flow of water, take up little cement, and thus give a deceitful effect of solidity, but which, with further sinking of the shaft, do not offer sufficient resistance to the pressure, and thus may ruin the shaft. So long as the water is not effectually held back by the cement, so as to furnish the conditions necessary for forming a cement wall strong enough to withstand the very heavy pressures to which it may, under some circumstances, be subjected, the danger of a break may still be detected by our instruments, even in cases where the almost complete cessation of flow would, according to previous experience, apparently justify the further sinking of the shaft.

CONCLUSION.

The foregoing remarks will, it is hoped, help to give the reader some idea of the principles underlying the various methods of investigating the interior of the earth by means of electrical waves and oscillations, and to stimulate his interest in the practical results thus far attained. These results will be discussed in another article.

[In addition to the article in *Kali* mentioned above, several accounts of the methods of investigation described in the foregoing memoir have been published by Dr. Leimbach and his collaborators in German and Austrian scientific journals, the more important being:

H. Löwy and G. Leimbach, "Eine Elektrodynamische Methode zur Erforschung des Erdinnern (Erste Mitteilung)," *Physikalische Zeitschrift*, 11, 1910, p. 697 ffg. *Ibid.* (Zweite Mitteilung), *Oesterreichische Zeitschrift für Berg- und Hüttenwesen*, 60, 1912, p. 627 ffg. and p. 640 ffg.

German System and Method*

The Effect of the War on Her Industries

THE significance of the two words "system" and "method," and of all that these words connote, has been demonstrated to the full in the present war by the Germans, who, with much pride and satisfaction, make innumerable references to them in the press, in public meetings, and in private conversation. We all know that Germany, in every conceivable field, has carried her principle of systematizing to a length and degree of perfection unapproached and, perhaps, even hardly attempted in other countries, and however difficult her position may be at the present day and in the future, it would have been infinitely worse had she not had her system of systems to fall back upon. Its immense machinery was at once put in action, and the Germans claim for it that, when put to the tremendous test set it by the war, it has done all that could possibly have been expected from it.

At the recent general meeting of the Allgemeine Elektricitats Gesellschaft a statement was made that "the first task for the German industry, which through the war had experienced an unprecedented 'narrowing in,' was that of standing on its legs. To do this, a transformation of the entire industry was to some extent necessary. Although it certainly was by no means a simple matter for a country with many imports suddenly to get substitutes, the necessary transformation or alteration within the whole industry has been completed with admirable ease." Commenting upon these remarks, a writer in a Berlin journal says this only confirms what every day and every hour they see and hear and read. There is hardly an industrial report which does not bear out that, after the shock, work has been resumed with 40, 50, or 70 per cent of the usual staff, and that part of the work, directly or indirectly, has been devoted to war purposes. A factory for incandescent lamps all at once took up the manufacture of cartridges; machine works made "Gullasch-cannons"; a maker of artificial flowers went in for bread-bags, a bijouterie concern for knapsacks; a hotel kitchen was turned into a jam factory. It only took a couple of weeks, and the necessary plant was available. Hands were trained, and energetic merchants looked to the supply of raw materials, or where the usual ones were unobtainable, of substitutes, and to means to bring producer and buyer in contact, though often by a roundabout way. The system has worked admirably, and at a time when people were compelled to work with the utmost economy it has managed to call forth from the darkest and narrowest corners raw materials, to secure that nothing was wasted, and that no possibly accessible foreign source of supply was neglected. The fact that a number of earnest and financially strong business men were compelled to apply themselves to opportunistic dealings has also helped to augment the exceptional work done in this connection.

In examining into the reasons why German industry has escaped being brought to a standstill by the war in nearly every one of its more important sections and, after a short reorganization and with partly altered objects in view, has worked on with an imposing certainty and without any suspicion of nervousness, it becomes clear that the most potent factor is that the German army quickly succeeded in carrying the war into foreign countries. In addition to this, the industrial and financial authorities succeeded, by wise measures, in establishing confidence in the power of resistance of the German industrial organization, which, in its turn, rested upon the German military successes. The causes of the uniform continuity in German industrial growth, however, in the last instance are to be found in the fact that German development, more than that of any other country, has grown systematically, and shows no gaps of any moment in the manufacturing processes. With regard to certain raw materials which the German soil does not produce, or, in any case, not in sufficient quantities, Germany will also in the future have to depend upon foreign countries, even if the efforts of its scientifically working industry are systematically centered upon replacing artificially the natural raw materials which Germany lacks. In this connection mention is made of the successful attempts at producing artificial nitrogenous manure instead of Chile nitrates, at producing home-manufactured benzol in place of foreign benzine, and of the not yet quite successful attempts at producing artificial leather and rubber.

Still more important than the raw-material question for the maintenance of the collective German industry under the present conditions is the fact that no indispensable intermediate link is missing in the large processes of production. Germany produces herself all her half-finished goods, and she utilizes the residuary products of her industrial processes for the manufacture of valuable auxiliary commodities with such financial results that no other industrial nation in the world even approaches her in this respect. What these auxiliary products mean to Germany at present is more especially demonstrated by sulphate of ammonia and benzol. How much the want of important links in production can harm a country in her industrial processes is demonstrated in England, where the inadequate development of many auxiliary and vital industries has almost crippled some of the country's chief lines of manufacture. Thus, the stoppage of the German dyestuff import, which, in money, only represents about a million sterling, threatens the English textile industry, the English wall-paper industry, and many other branches, with a turn-over of many millions. In the same way the absence of cheap German half-finished goods has deprived the English iron industry of an important intermediate link. Further, the stoppage of mining timber has gravely inconvenienced the collieries.

Industrially, the long established and growing British principle of producing entirely finished goods, and importing the raw and intermediate products of great industries, has proved inferior to the German method in time of war. This latter aims at a complete organization of an entire manufacturing process in comprehensive works, which, separately or together, cover the entire series of operations needed. The industrial expansion of Germany, although it is much younger than that of England, has been laid out on more systematic lines, and in such a way as to render the country more independent of foreign aid. Under the difficult and strenuous conditions of war it has demonstrated the extreme value of system and method, and the advantages which they confer on a nation when it is cut off from the lands from which it draws its raw materials.

*From Engineering.

The Government to Certify Timepieces

THE test and certification of watches, chronometers, and other timepieces has been carried on for many years at the Kew Observatory in England, at the Besancon Observatory in France, and at the observatories of Geneva and Neuchatel in Switzerland, but no such tests have been made for the public in this country, except for a few years at Yale University many years ago. This line of work is now started at the Bureau of Standards, and Circular No. 51, entitled "Measurement of Time and Tests of Timepieces," has just been issued giving the regulations under which the tests will be made, the methods employed, together with sections on the use and care of watches, and on standard time and the sources of reliable time standards with which one may make frequent comparisons of his watch. This first edition of the circular announces the regulations for the test and certification of watches only; the test of other timepieces will be taken up later. It is expected that the tests will be especially valuable in cases where watches are to be used for scientific purposes or exploration, and also to purchasers of high grade watches in giving them assurance that the watch is reasonably adjusted and in good condition at the time of the test. Copies of the circular and also of the application blank may be obtained upon request from the Bureau of Standards, Washington, D. C.

The Hydraulic Mining Cartridge*

A Mechanical Device for Use Where Explosives Are Impossible

By James Tonge, M.I.M.E., F.G.S.

The difficulty of removing rock and other material, in places where the shock attendant upon blasting operations would be damaging and dangerous to surrounding strata or foundations, is one which has not hitherto been thoroughly overcome.

The enormous initial power generated by the sudden decomposition of explosive substances has enabled great quantities of natural or artificial beds to be displaced, and a great portion of the work of the civil and mechanical engineer is involved either directly or indirectly in operations of this kind. The objection to the use of explosives, however, in many circumstances, is that the effect of blasting can seldom be harnessed or controlled so as to prevent the disintegration of the material beyond the area which it is desired to dislodge. In the case of many metalliferous mines, and sometimes of quarries, this is not a great drawback as it may not only be unnecessary to limit the operation of the "shot," but it may be actually desired to have the material in a pulverized condition. Even in this case, however, it should be remembered that this is not an economical means of

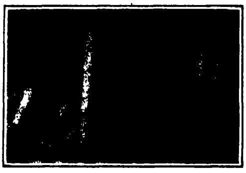

Fig. 3.—Operating the hydraulic cartridge in a coal mine.

obtaining such a result, for pulverization by explosives involves enormous waste of power as it usually represents great excess of explosive charge; in other words, the use of explosives must involve either the risk of accident through an insufficient charge or the production of misapplied energy.

It is for the purpose of avoiding these drawbacks and in order especially to take greater advantage of natural lines of cleavage or of bedding in the material to be dislodged that efforts have from time to time been made to provide what may be termed more rational or scientific means in the shape of mechanical substitutes for blasting.

The simplest form of mechanical means for breaking ground is, of course, the wedge, and this is used in varying lengths and shapes, in metalliferous and in coal mining, in all parts of the world. Various improvements on the simple wedge have been used at various times, viz., the stub and feather and the multiple wedge. The former consists of a steel "stub" or wedge driven in between two tapered liners of steel called "feathers" which have their thin end near the front of the hole. The multiple wedge is placed in a hole previously drilled and has liners also, but a pair of "feathers" may be inserted between them, driven up as far as possible, and then a second or a third "feather" may be used until the rock or coal is broken down. In coal mines, special efforts have been made to devise mechanical wedges capable of breaking down coal, notably those invented by Bidder, Burnett, Shreeve and Hall, and these have been used to a greater or less extent in a few mines. In some of these the wedge was driven in by means of a screw and handle, like a hand drilling machine, and in one case by hydraulic power.

These machines are not now in use and it may be taken that they have proved to be impracticable. This is no doubt due to the great pressure put upon them, even under favorable conditions, and the difficulty of devising and supplying a hydraulic pump capable of working at high pressure for a considerable time. It must also be remembered that a mechanical wedge must perform more work than that required to wrest the rock or coal from its position, as a certain amount of power is consumed in overcoming the friction of the sides of the wedge as it is driven up. Again, it is a disadvantage to have the material at the front of the hole breaking away as the wedge enters—the full weight of the falling material should, if possible, be utilized to assist the operation. With this object in view, machines have been designed to operate at the back of the hole first, the wedge being drawn towards and not driven from the front. Except in the case of the simpler forms it may be said that no mechanical wedges are now being used with success for excavating purposes of any kind.

The Hydraulic Mining Cartridge.—The hydraulic mining cartridge differs from all other mechanical substitutes for blasting. It is not worked on the principle of the wedge, and consequently the power expended in forcing a wedge into the hole is saved. Instead of employing

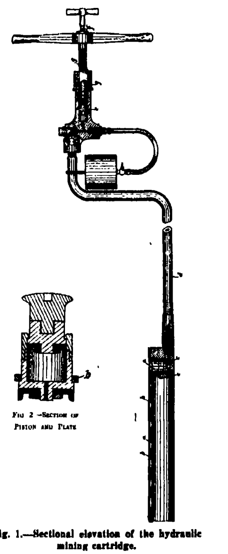

FIG. 2.—SECTION OF PISTON AND PLATE

Fig. 1.—Sectional elevation of the hydraulic mining cartridge.

a wedge, the disrupting effect is obtained by means of a number of small rams or presses working at right angles from a strong cylinder of steel. (Fig. 1.) In order to make these rams more effective in their operation, by obtaining a greater travel from their original position, they are made of a duplex or telescopic form, one part sliding and fitting upon the other (Fig. 2). In some cartridges these pistons operate from each side of the cylinder alternately, thus greatly increasing the travel. To retain the rams in position, a sliding plate is used fitting in grooves in the barrel (*b* Fig. 1); this is so formed and secured that it is perfectly rigid and firm when the machine is in operation, but is readily removable if it is desired to detach or replace any of the rams. By a suitable arrangement of passages (*c* Fig. 1) a communication is made between each of the rams, whereby simultaneous action is obtained. Machines are made of various diameters, viz., 2½ inches, 3½ inches, and 4 inches, and of various lengths, say with 8, 6 or 5 rams, the smaller diameters having the larger number of rams. Pressures of 3, 4, or 5 tons per square inch are usual, so that machines are made to withstand great stresses.

The Pump.—The cartridge is operated by means of a pump (Fig. 1) to which it is directly connected by a pipe (*d*). The pump is of special design. At the commencement of the supply of water it is desirable that the latter should be supplied in such quantities as to fill up quickly all the spaces within the rams and passages, while at the same time allowing the operator, when the rams begin to move and the pressure to increase, to supply a less quantity of water, but at a greater pressure, to complete the final operations of the rams. This is done by having the piston (*e*) operated by the piston rod (*f*) which passes through a supplementary or hollow rod (*g*) and has an appropriate handle for operating the piston within the pump cylinder. By these means the piston may be quickly reciprocated by the user moving the small handle until the desired quantity of water has been supplied or until the pressure to be exerted over the rod (*f*) is beyond the power of the user, when the supplementary rod (*g*) may be brought into use to finish the operation, this advancing by screw motion, and great pressure being obtainable in this way.

Method of Working.—After the rock or coal has been prepared with one or more loose sides and the drill hole of 3 inches, 3½ inches, or 4½ inches, has been drilled to a suitable depth (say three or more feet), the cartridge is pushed in with liners if necessary. The water tank is filled and hung on the pipe, the rubber suction pipe coupled, and the taps turned. The small handle and then the large one are operated as already described. The pressure being fully on, the enormous power of the apparatus is soon apparent, for the rock or coal is heard to

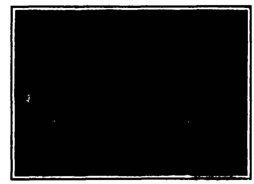

Fig. 4.—Effect of hydraulic cartridge on rock in mines.

be rumbling and cracking. This is allowed to continue until the breaks are of such a size that the mass can be pushed or pulled over and usually is in such condition as to be easily and safely handled.

Line of least resistance.—It is easy to understand that when a shot is fired in rock or concrete, the direction of the breakage will be chiefly in the line of the weakest part. If the material is of uniform strength this direction would be a straight line from the explosive to the nearest unsupported edge. But stratified beds, seams of coal, and walls of stone or brick, are not usually of uniform strength; rock and coal beds contain breaks, cleats, and faces, while concrete beds are invariably irregular in constitution or structure. It follows, therefore, that the line of least resistance is not necessarily the shortest line from the charge to the surface. The difficulty and danger of explosive firing is that whatever this line may be, it is not often possible to make use of it; the pressure generated, though not equally effective, is equally applied in all directions owing to the instantaneous character of the decomposition. This involves high temperature in the explosive gases, a large portion of the heat being absorbed and wasted in the portions which are not capable of being blown down. When mechanical means are employed the time involved in the operation allows the whole of the power to be exerted and applied in the desired direction without waste of heat energy. Not only is power lost in heat energy in the case of explosive compounds, but the result often proves that there has been counter action whereby the rock displacement is reduced through one line of force operating against another, closing in or reducing the area of broken ground.

In practice it is found possible so to arrange the hydraulic cartridge holes as to enable much greater areas of material to be moved than could be done with a safe quantity of explosive, while in some cases the displacement has been greatly extended by the use of small-sized bore holes toward which the slowly developing line of least resistance can assert itself. In other words the power exerted by the rams can be controlled, after a little experience, so that the full pressure can be usefully applied.

Use in Mines.—The appliance was originally introduced into mines in order to supply the acknowledged need of a different method for bringing down coal in mines in the best possible condition after it had been undercut by hand or machine. The use of high explosives for this purpose, apart from the element of danger, has

* From the *Journal* of the British Society of Engineers.

always been considered undesirable by mining experts, because in using them coal is shattered and wasted and dust made. Now that coal has to be won from greater depth than formerly, and the distances and areas underground increase, the dangers and extent of explosion have proportionately increased, as many recent colliery disasters have shown. The mines in which the cartridge has been chiefly adopted may be divided into two classes:

(a) Where the coal is so friable as to render the use of explosives impossible for commercial reasons.

(b) Where the condition of the mines in regard to gas, etc., renders shot firing an exceedingly dangerous proceeding.

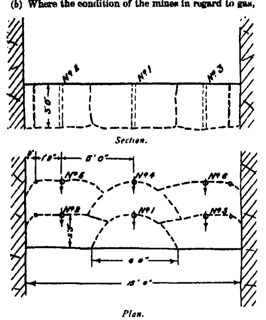

Fig. 5.—Trench Excavation.

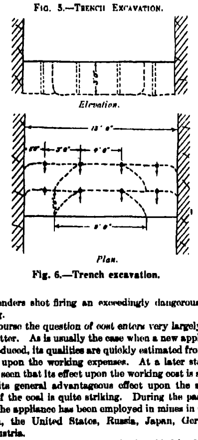

Fig. 6.—Trench excavation.

Of course the question of cost enters very largely into the matter. As is usually the case when a new appliance is introduced, its qualities are quickly estimated from the effects upon the working expenses. At a later stage it will be seen that its effect upon the working cost is slight, while its general advantageous effect upon the selling price of the coal is quite striking. During the past ten years the appliance has been employed in mines in Great Britain, the United States, Russia, Japan, Germany and Austria.

In removing coal a series of holes is drilled in the top of the seam, adjoining and running parallel with the roof. These holes are at intervals determined by working conditions, usually from 6 feet to 10 feet apart and from 3 feet to 5 feet deep. The operator begins at the first hole and pumps off each in succession, usually leaving the supporting sprags to be removed by the collier, who fills the coal thus broken and prepares the coal behind for a repetition of this process. One operator can pump from 30 to 40 shots per working shift of eight hours, using only one machine, which lasts with repairs from three to four years. This procedure is adopted where a large wall of coal has been opened out, and where the coal is got in pillars and headings the process is somewhat modified. The coal across the face of the heading is undercut (almost universally now by a percussive machine operating from a fixed standard) and a vertical slot or "shearing" is cut up the center of the coal, thus providing a loose end. One hole on each side of the "shear" is then sufficient to bring down the coal. The holes are placed as near as practicable to the fast side in order to bring the coal down as near the "fast-corner" as possible. (Figs. 3 and 4 show the cartridge in use in mines.)

Among the mines in which these machines are at present in use are the following:

Colliery No. 1.—At this colliery an average of over 1,000 explosive shots per week were formerly fired in coal in the various mines. By the introduction of the hydraulic cartridge the whole of the explosive shots have been discarded and there is not now a single shot in coal in any seam. In one seam alone a total of 28,500 hydraulic cartridge thrusts were made in one year, by which it is estimated that 92,026 tons of coal were produced, or about 3¼ tons per thrust. The seam was 3 feet thick and four cartridges were in daily use.

Colliery No. 2.—In a seam using five hydraulic cartridges 450 tons of coal are produced per day, of which 75 per cent is large coal and 25 per cent small. When the coal in this seam was brought down by explosives the percentage of large coal was 65 per cent and the percentage of small was 35 per cent. The average price of large coal was 13s., and of small coal 7s. per ton. The profit obtained by the use of the cartridges on this seam on 450 tons is therefore £14 5s per day. Fifteen machines are employed at this colliery, making a total advantage over explosives of £42 15s. per day. Moreover, an extra 6d. per ton is obtained for the coal brought down with hydraulic cartridges, on account of its greater hardness and freedom from dust.

Use in Reservoirs, Docks, Harbors and Canals.—The operations in these places have all certain features in common which allow of their being classed together, and they may be divided into three classes.

(a) *In open Trenches.*—The difficulty of removing rock from confined spaces where it is necessary that no shock or vibration should be transmitted to surrounding strata is a very vital one. The introduction of the hydraulic cartridge into this class of work will, it is hoped, help to solve this question. During the past few years it has been thoroughly tested under most varied conditions and in all classes of deposits.

The work in trenches usually proceeds as follows: A number of holes are drilled (Fig. 5), say 2 feet 3 inches back from the edge of the rock, about 5 feet apart and 3 feet to 5 feet deep, according to circumstances. The holes are, when possible, bored by a power drill operating from a tripod. By these means suitable holes, of diameters up to about 5 inches, can be quickly drilled. The center hole is pumped first and provides a loose end for those on each side. These are pumped in turn until the fast side is reached, where it may be found advisable to drill a small 1-inch diameter hole, say 9 inches from the fast side, to enable the cartridge to break the rock as close to the fast side as possible. Sometimes this method is varied by pumping off two center holes simultaneously and placing the last holes 2 feet from the fast side, leaving out the small diameter holes. (Fig. 6.) In this case the holes could be 2 feet 6 inches from the front edge and two machines would be required.

Taking a trench 15 feet in width and holes 3 feet in depth, the first method would necessitate three cartridges and two 1-inch holes to get 100 cubic feet of rock, while the second method would require only four cartridge holes to remove 112 cubic feet. During the operation of the machine it is possible to see the rock slowly fracturing at each turn of the handle. Work of this character has been done by the cartridge in connection with the Derwent Valley Water Works, and the Cwm Taff Reservoir, Liverpool Corporation, and tests are now being made for the Abertillery Water Scheme.

(b) *Under Water.*—The appliance has been used in many cases under water, chiefly to remove rock, either from the sides of canals, or from the sides of harbors and docks, where it was obviously impossible to use explosives, the machine being operated from the bank or from pontoons. A typical case will serve to illustrate the suitability of the cartridge for this class of work. The rock to be removed was partly projecting from the side of the canal, and it was necessary not only to remove the mass in the water, but also that upon the bank, as shown in Fig. 7.

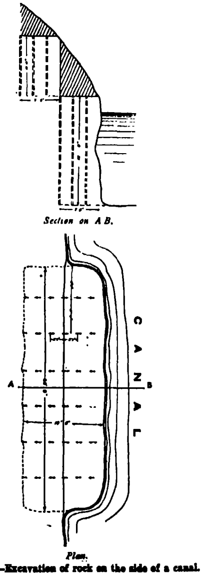

Fig. 7.—Excavation of rock on the side of a canal.

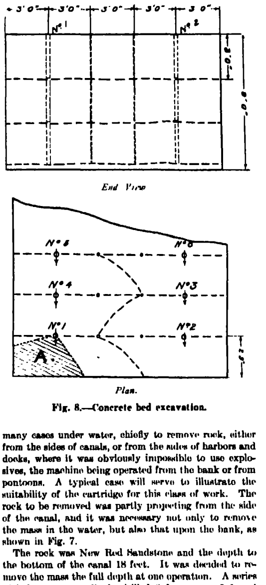

Fig. 8.—Concrete bed excavation.

The rock was New Red Sandstone and the depth to the bottom of the canal 18 feet. It was decided to remove the mass the full depth at one operation. A series of holes was accordingly drilled 6 feet apart, 2 feet 4 inches back from the edge, and 18 feet deep. These were pumped off in succession and the operation of the cartridge at this depth sufficed to break the rock right up to the bank in nearly every case. In one or two holes it was found necessary after operating in the bottom half to draw the machine up about 9 feet and operate again. During the operation divers were below water ascertaining the position and extent of the breaks and directing the operator above as to how to continue the thrusts. The portion shaded (Fig. 7) was removed by hand, and another series of holes was put down 10 feet deep, 6 feet apart, and 2 feet 4 inches from the edge, to break up that portion of the rock to be removed.

In the Alexandra Docks at Newport, and in the new dock at Swansea, the appliance has been used to break up ledges of rock occurring in the vicinity of walls which would have been damaged by the use of explosives. The holes were put in and the cartridges inserted under water by divers and pressure was applied from the pump placed on a raft on the water.

(c) *Dock or Harbor Walls.*—Hydraulic machines have been used for some years at the Dover Harbor Works for the purpose of detaching the large concrete blocks used in the harbor walls. These blocks are of great size and weight. By inserting the drill hole along the bottom of the block and placing the cartridge about half-way under it, the whole mass is slightly lifted and tilted without breaking, and being thus released from its bed is easily lifted on to a wagon by a crane. Machines are being used for a similar purpose in other docks.

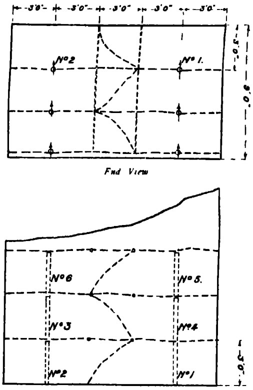

Fig. 9.—Concrete bed excavation.

Excavation of Foundations.—The question of the removal of concrete foundation beds by a method which would not involve explosive blasts and would avoid the slightest damage to machinery or buildings has been carefully studied recently by the writer, and had never been thoroughly solved until extended trials in all parts of the British Isles had been made.

The effect of powerful hydraulic pressure upon concrete is interesting. In the case of sandstone and shales there is comparatively slight crushing of the rock before the full pressure of the rams has the effect of causing the mass to bend; considerable pumping and consequent travel of the rams is then necessary before the rock finally begins to crack and break away; with concrete, however, there is usually a perceptible interval during which the rams are crushing or compressing the material and no movement is noticeable; after this is accomplished a few more thrusts of the rams cause the whole mass to break up without any indications of bending. It may still be necessary to continue to apply pressure and to increase the size of the breaks in the mass, but the greatest shattering effect will have been accomplished at the first disclosure of the cracks, the pressure required to break the mass afterwards gradually diminishing.

In such material, explosives invariably have the effect of "hacking a way through" by the shortest direction to the unsupported edge (Fig. 8), pulverizing the mass but failing to take advantage of pressure gently applied, by means of breaks which spread and widen, and to utilize the weight of the concrete itself to increase the scope of the operation. Numerous experiments in this class of work show that 60 to 70 cubic feet of concrete can easily be removed per thrust.

The general procedure in attacking beds of concrete may be divided thus:

1. By vertical cartridge holes.
2. By horizontal cartridge holes.

1. *By Vertical Cartridge Holes.* (Fig. 8.)—This method is most applicable to places where power can be easily obtained to bore the holes by tripod and power drills. The cartridge holes are drilled about 3 feet deep and 2 feet 9 inches back from the front edge of the bed. It has been found of great advantage to drill small diameter holes 3 feet away and in line, to which the fracture will break. In this way a bed 15 feet wide could be broken all across by two cartridges and two small diameter holes, amounting to 124 cubic feet of material.

2. *By Horizontal Cartridge Holes.* (Fig. 9.)—In this case the holes would be 3 feet deep and made to lift 3 feet of material per thrust, the vertical small diameter holes being put in as before. The amount of material moved per thrust is 67 cubic feet. The effect of lifting up is to break a larger quantity of material and in much larger pieces than is the case with vertical holes. With the latter the concrete is found to be very well broken up, and ready for handling without the further use of tools. Horizontal holes, on the other hand, are more suitable for beds where foundation bolts are embedded in the concrete.

There appears to be no class of work so suitable for this machine as the removal of concrete beds. The following recent case is a typical example. At a municipal electricity works the cartridge was used to remove the main engine room foundation bed. Within a radius of 40 yards from the scene of operations, many of them within the same building, were very valuable Lancashire and water tube boilers, electrical and steam engines and the main switch board and cables. Needless to say the work had to be carried out with as little vibration or shock as possible. Explosives were out of the question, and the ordinary method of hammer and wedge would have proved an extremely long, tedious, and expensive process. The bed consisted of a solid mass 14 feet 6 inches wide, 26 feet long, and 10 feet deep, composed of hard cement concrete for the most part, and reinforced with numerous foundation bolts.

It was considered unnecessary to install power drills on the work and the holes in consequence were drilled by hand. The majority of these were horizontal and were put in by means of an ordinary twist drill and ratchet machine by two men. These men could drill fairly easily 3 feet per hour. One hydraulic cartridge only was employed. The general procedure was to keep the drillers at work putting in holes all round the side of the concrete, the machine following when two or more holes were ready. The holes were on an average 6 feet 6 inches apart, and from 2 feet 6 inches to 3 feet below the surface in the case of horizontal holes. The vertical holes were drilled only in special places to trim down the vertical edge, and in these cases the measurements were about the same. The employment of shot holes to form a breaking point was considered unnecessary. (Fig 10 is a photograph of one of the horizontal shots.)

The debris thus broken was removed by a gang of six men who were kept busily employed with pick and shovel, and wedges were necessary only to break up the larger pieces to a suitable size for handling. It was found that the amount of material broken up in the course of three or four shots was quite sufficient, in consequence of the limited and cramped working area, to keep the men busily employed for the rest of the day. Had it been possible to place more men on the bed, there is no reason why a much better output should not have been attained, but in this case it would have been necessary to break open the wall in several places, which was not considered advisable. The whole bed, weighing approximately 200 tons of concrete, was removed in twenty working days. About sixty shots were necessary to complete the work, making an average of nearly 3½ tons per thrust.

The cost of the work was as follows:

Labor per day, including operator, drillers, navvies, and foreman	£2	15	0
Amount of material removed—average 10 tons per day . . .		4	9 per ton.

The above cases will be sufficient to show that with a mechanical substitute for blasting capable of exerting a total pressure of 150 or 200 tons upon rock, coal, concrete, masonry, etc., and in such manner as to cause no shock to the material in which it is operated, there should be possibilities of usefulness to engineers not previously contemplated.

Replying to the discussion, the speaker said that one speaker had referred to the use of black powder for blasting salt rock. That was really in line with the use of the hydraulic machine, which operated slowly and gradually. The old-fashioned explosives had the very distinct advantage that, owing to the length of time required before the gases attained their full temperature and pressure, it was possible to get the power exerted in a more effective way. He thought that if it were not for the element of danger associated with black powder, all users of explosives would agree that the old-fashioned slow-working explosives had always been most satisfactory. It was only carrying the principle a little further to apply it in the form of hydraulic power.

With regard to Mr. Jenkins' point, rotary drills had been used for making holes on many occasions, and it had been found that the diamond drill was quite satisfactory when used as a hand machine. It was very necessary to have a regular and smooth hole, and the diamond drill gave such a hole much better than any percussive drill could possibly do. It appeared to him that it would also have the effect of greatly reducing the amount of dust that would be made in the drilling of the hole, and not only would there be a smaller quantity of dust made, but that dust would be of coarser texture.

As to the driving of headings, he must say that in ordinary tunneling he had not been entirely successful, chiefly because of the difficulty of obtaining a suitable drill for putting holes in easily and quickly. It was not possible to blast from the solid. If the rock was to be broken with a loose end at all, it was necessary to be able to put in small holes readily and easily in various directions. Having loosened one side, there was then no longer any difficulty.

With regard to the limit of 150 to 200 tons, he mentioned those amounts because they were approximately those to which he had worked up to the present. By using the 3-inch machine he got, with full pressure on, about 120 tons. When using a 4-inch machine he generally used about five pistons instead of eight, and he got 170 or 180 up to 200 tons pressure with that particular size. There was no limit. It was possible to increase the pressure according to the length and size

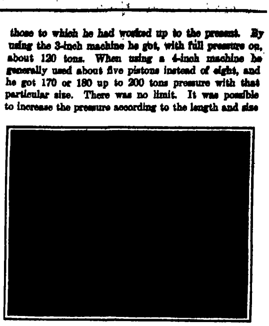

Fig. 10.—Hydraulic cartridge used in a bed of concrete.

of the machine, but there would arise a liability for the cartridge to become bent. There was no bending of the cartridge if the sizes of the machines used were limited as at present, provided that a regular hole was obtained. If the hole was not regular and smooth there would be the risk of some damage being done to the machine. He did not mean to say that there was a danger of bending the machine after the material had once been broken. When the back of the material was broken there was no danger to the cartridge. Very few machines had been bent or damaged in any way. That was probably due to limiting the length of the cartridge to 20 inches in the case of eight-piston machines and a few inches less in the case of a five-piston machine.

With regard to varying the intensity of the pressure, he thought that that was hardly necessary so long as the hole was drilled sufficiently deep. He did not like to have the end of the cartridge anywhere near the end of the hole. It should be right in. As long as it was right in the hole there did not seem to be any advantage to be gained by varying the pressure. He got the cartridge right into the hole, and then it was not necessary to make any change. Usually the pistons were out an equal distance throughout the full length of the cartridge, showing that the resistance had been the same throughout its length.

The Flight of a Golf Ball

Some interesting statements concerning the flight of a golf ball were made in a case heard by Mr. Justice Warrington in the Chancery Court. The validity of the patent granted to William Taylor for his golf ball was challenged by Messrs. A. W. Gamage, Ltd., who claimed the revocation of the patent owned by Charles Stuart Cox and A. G. Spalding & Bros., who made the golf ball under the name of the "Dimple." In the specification of the patentee, he said his principal object was to obtain better results in the flight of the ball in the direction of a sustained hanging flight, giving a flat trajectory, with a slight rising tendency toward the end of the flight.

Prof. C. Vernon Boys said the form of the surface of the ball affected the flight very materially, and, from general experience, a smooth ball had been found not to be so good as one of which the surface had been roughed. The smooth ball had not an advantageous surface for getting a long travel. The character of marking which constituted Taylor's invention was an inverted bramble pattern, and consisted of isolated cavities, circular, evenly distributed, shallow, and their sides steep. Prof. Boys said he found by experiments that this form of surface gave an extremely satisfactory flight. The experiments consisted in driving the balls by means of a machine designed by himself and Mr. Taylor, and were carried out on Borstall Golf Course, on the road to Charnwood Forest. He did not find in the specifications of Willie Park and Fernie, on which Messrs. Gamage relied, Taylor's form of cavities.

In cross-examination as to the typical golf ball's flight, witness said the ball more than counteracted the action of gravity. His Lordship: The golf ball does not make a parabola? Prof. Boys: Not in the slightest degree; a good flight is very nearly straight for a long time, and then gradually rising and then falling. His Lordship, giving judgment, said that the main feature of the descriptive part of Taylor's specification was its vagueness. He held that the patent failed, and that there must be an order for its revocation. A stay was granted pending an appeal.—From the English Mechanic.

Snow Removal*

Report of the Conference Held in Philadelphia, April, 1914

EARLY in March, 1914, Mr. Morris L. Cooke, Director of the Department of Public Works, Philadelphia, wrote to a number of the leading eastern cities suggesting the needs of a conference on the subject of snow removal and pointed out, that in view of the very apparent lack of engineering methods generally employed in a problem which so clearly calls for engineering study, it might be profitable if those in charge of the matter of snow removal in the larger cities could be brought together, and that at least an approximation of a definite policy of snow removal might result from such a meeting. The suggestion met with such favor that a snow removal conference was held in Philadelphia on April 16 and 17, 1914.

A Committee on Resolutions, J. W. Paxton, chairman, was appointed to submit a report, which would be the result of papers, discussions and recommendations made at this conference, and the committee makes the following report:

The problem of snow removal must obviously be considered differently in different cities as its solution is dependent upon such variable elements as climate, population, width of streets, density and character of traffic, location of sewer systems, available disposal places and other local conditions, to say nothing of the financial policy of the municipality.

It would seem impossible to formulate anything but the most general suggestions, and yet it is found that even so vital a matter as the financial policy does not affect the main problem, except in the extent of the work.

The work of snow removal is generally done by contract under the supervision of city officials, payment being made according to the quantity removed as tallied by wagons hauling to the disposal dumps, the forces and equipment consisting of men with shovels, horses and wagons. In some cities, scrapers and plows are used to push the snow to the side of the street, relieving traffic and making it easy to pile, or to load without piling.

Salt is generally and very extensively used for the removal of snow in Liverpool, London, Paris and other European cities. The very general practice is to broadcast coarse salt on the streets during and immediately after a snow storm, and when the snow has been reduced to slush by the action of the salt, the streets are flushed with water and the slush washed down the sewers; but in those cities they do not have very heavy snows and it is doubtful whether it would be practicable here where we have a much greater depth of snow. There is also a very serious objection to the use of salt by the Societies for Prevention of Cruelty to Animals and in some of the cities it is prohibited by ordinance. It is questionable whether the use of salt has been given a fair trial in this country for the removal of snow and there is little doubt but that it would be useful in light snow storms.

Much thought has been given to the design of apparatus for melting snow, and also, to special machinery for scraping, loading and transporting. Inventors, designers and manufacturers should be encouraged to continue in the endeavor to produce equipment which will render practical and efficient service, but the amount of snow is so variable and the equipment is in use for such a short period of time that it is desirable it be designed to be useful for other work at different seasons of the year.

The problem confronting the public officials is the removal of snow in the shortest time in such a manner as not to interfere with traffic, and at a minimum cost. Therefore, using the method of scraping, shoveling into trucks or carts and hauling to dumps, the length of haul becomes a most important factor and it can readily be seen that the utilization of sewer manholes as dumps, and the sewer system to carry the material to the rivers, is the most economical method which can be devised as it reduces both the haul and the handling to a minimum. The authorities in charge of the sewer systems have, as a general thing, apprehensions regarding the use of the sewer as a snow carrier. The Borough of Manhattan, New York, Bureau of Sewers, however, made experiments during the winter of 1914 which seem to prove that, within certain limits, such apprehensions are ill-founded.

Gas and chemical combinations in the sewers have little effect on the rate of melting. Two cubic yards per minute is the maximum rate at which snow can be shoveled into a 24-inch manhole. Tidal sewers can only be used to advantage when the tide is low, in which case the factors of the ordinary sewer apply. Siphon sewers can be used as well as the ordinary type.

Where difficulty is experienced with an insufficient flow in the sewers, or where the flow decreases or stops, the water plug may be opened in the drainage area of the sewer above the manhole in use, until the volume of water is sufficient to carry off the snow, but it has been found that the most efficient use of water may be had where water jets are constructed in the manholes into which the snow is dumped. The problem of getting the material into the manholes in the least time with the least interference with traffic opens up a field for the consideration of a special form of manhole to be used satisfactorily for this purpose. Pittsburgh and St. Louis both use a special form of manhole.

The committee gave further an account of the work of snow removal in the cities of Philadelphia, New York, Boston and Scranton, and also of the Public Service Railway of New Jersey, and the Pennsylvania Railroad Company, on which they base the following conclusions:

1st. The plan of organization and the system to be employed should be worked out in advance of the snow season. This preliminary work should involve: (*a*) a plan of co-operation among all branches of the municipal government; (*b*) the formation of a skeleton organization composed of all the available city forces, such as engineers, inspectors, time-keepers, laborers and teams; (*c*) the division of the city into zones and the determination of a definite method of work for each zone. The various members of the organization should be assigned to these zones and the responsible officials familiarized with the duties expected of them.

The character of work to be performed in the different zones may consist merely of the regulation of opening cross-walks and gutters and otherwise generally assisting pedestrian traffic and the run-off of the snow, or it may consist in the complete removal of the snow from the streets. Owing to the general increase in motor traffic and the concentration of business in definite office districts and to the general public demand for increased urban facilities, the present tendency is to increase the scope of the work involving the complete removal of snow from all main thoroughfares and business streets.

2nd. Removal work should commence as soon as the snow has covered the pavements and the indications point to the storm continuing, and should be carried on continuously. This as a principle is successfully followed by street railways and by some cities.

3rd. The carrying capacity of the sewer system should be utilized as far as possible.

The use of the sewers which reduces both the haul and handling to a minimum involves two operations: namely, getting the material to the catch basins or manholes, and then putting the material into the sewers. The first operation can best be done by loading into wagons or trucks and hauling to suitable manholes or by the use of scrapers or graders. The problem of getting the material into the manholes in the least time and with the least interference with traffic opens up a field for consideration of the question of special forms and special locations of manholes designed to be used solely for this purpose.

The method of flushing the snow with fire hose into catch basins may have a limited application but it is too unreliable to have any general value as it depends on weather conditions.

4th. When practicable, where there is only a small area to be cleaned, the work should be performed directly by the municipality by day labor. This method of operation is the most flexible and the most easily administered and it obviates the necessity of measurements and checking involved under the contract system. The work can also be performed by day labor in large areas by adopting the following method: The department to advertise and go out into the open market and hire teams to haul the snow for so much per yard, the price to be determined by the department and to represent a fair estimate of the cost of the work and a fair profit. This, of course, would throw the work open to anyone owning one team, or a hundred or a thousand or more teams, depending upon the amount of work to be performed, and would not leave the department dependent upon any one or more contractors. In this method, as well as when the work must be performed by contract system, a method of measurement as simple and accurate as possible should be used. The practicability of having work done by the municipality will depend among other things on the immediate availability of an appropriation. It is essential for the proper conduct of the work whether by day labor or contract that appropriation for snow removal should be made in advance of necessity for the work.

5th. Co-operation should be sought with the traction companies and use made of adjustable plows and sweepers to open roadways adjacent to street railway tracks at the time that the work of clearing the tracks is being carried on.

6th. Effort should be made to obtain the co-operation of the public and to instruct the householders in the method of the removal of snow from private premises in such a way as to least impede the city's work. Where sidewalks are of greater width than would be necessary to handle the reduced volume of pedestrian traffic, which may be expected after a heavy snow, the snow instead of being entirely cleared from the sidewalk and piled in the roadway should be left on the sidewalk near the curb line to be later removed by the city when opportunity presents itself.

7th The police force of the city should co-operate with the street cleaning force and the services of patrolmen as inspectors should be utilized as far as possible. The police in particular should give attention to the enforcement of regulation governing the removal of snow from the sidewalks or from a portion thereof.

In a written discussion Mr. J. T. Fetherston[1] remarked that New York City has tried almost every method of contracting for snow work, from the area system to the direct haulage method on vehicle capacity basis Dividing the city into relatively small districts, larger districts and boroughs has been tried, and it would appear that the responsibility and experience of the contractor were of greater importance than the area or district assignments. In other words, an experienced contractor, with the nucleus of the necessary snow removal equipment, as a rule is in better shape to remove snow rapidly and control sub-contractors than is the municipality. More important still, he usually has sufficient control of funds to pay promptly all men employed. It would seem that experience, control of equipment and responsibility are the main factors to be considered, rather than the area basis, for the assignment of contracts

The statement of general principles contained in the committee's report would be clarified if the work were separated into these divisions. (1) contract work, (2) street railway assignments, (3) municipal work. Necessarily under each head should be given the plan, and every reasonable contingency covered by the assignment of the most suitable means of snow removal adapted to particular areas, streets or districts of the city under consideration. All municipal departments should be called in to assist the street cleaning division by the assignment of officers for the supervision of contract work particularly, leaving the street cleaning department as free as possible to perform the work for which its own force is best fitted.

As a general comment on the committee report, it is suggested that, if possible, engineers or street cleaning officials should receive from an authoritative source, such as the society, a summary of conclusions covering:

(1) A statement as to what types of streets should be cleared of snow, and how far the municipality is justified in removing snow from minor thoroughfares at public expense.

(2) A statement setting up the reasonable depth of snow for which a municipality should have equipment available, and in general the time limits within which streets should be cleared, so as to avoid economic loss. Coupled with this, a maximum depth of snowfall beyond which all citizens and transporting agencies should be required to place their services at the disposal of the municipality at cost.

(3) A compilation of snow statistics for various parts of this country, and if possible a summary of attending weather conditions.

Each city must work out its own salvation regarding snow removal and disposal methods. The problem is so complicated by uncertainty as to weather conditions that no particular method is best fitted for all cities and all conditions.

E. D. Very,[2] in a written discussion, pointed out that an endeavor should be made to define the extent to which snow removal should be carried on in a municipality. This definition should not be made in units of mileage or of square yardage but rather in terms of necessity. In this regard the financial policy so affects the main problem as to deserve considerable study, as the extent to which the work shall be carried on depends largely upon the amount of money a municipality can afford to spend. This question must be answered before we may assume that the area to be cleaned has been decided upon and the appropriation of money must be predicated upon an understanding of the actual need in this regard. We should go further and discuss the manner in which funds for the work should be raised.

[2] Sanitary Engr., New York

It is suggested that the tax for such purpose should be levied; a part by a general tax and a part by tax on property immediately benefited. Such a method would restrain the indiscriminate demand for unnecessary service for personal benefit.

W. Goldsmith[1] called attention to a statement in the report where mention is made of enlarging manholes for the quick disposal of snow. In the Manhattan experiment it was shown that two cubic yards of snow per minute can be shoveled into a 24-inch manhole and that 2,500 cubic yards were dumped into one sewer by means of three manholes in an 8-hour day. This seems to indicate that a 24-inch manhole is large enough. Besides, the effect of an enlarged manhole on the pavement must be considered, the majority of defects in street surfaces being due to manholes of one nature or another and it seems that the elimination rather than an increase of these enemies to pavements should be striven for.

F. Kingsley pointed out the fact that the same old cart-and-horse methods for snow removal seem to be used that were adopted when the problem became serious some 20 years ago. It is interesting, however, to note the success of the snow-melting device on the Pennsylvania Railroad, because the melting of snow seems to be the most likely path along which improvement can take place.

The cost of fuel to melt snow is only some 15 per cent of cost of handling it under present methods. The basis for this is that a cubic yard of snow as removed weighs approximately 1,000 pounds and would require about 200,000 British thermal units to reduce it to water, allowing a liberal margin over the latent heat of ice. Coal at $4 per ton provides about 67,000 British thermal units for one cent in a perfect furnace, or 27,000 British thermal units with 40 per cent furnace efficiency. At the latter rate the fuel cost for melting would only be 7½ cents per cubic yard or 15 per cent of the present apparent cost of handling it. This does not include interest or labor charges but these ought not to be insurmountable obstacles.

The problem is peculiarly one that mechanical engineers should be able to solve. It appears to be largely a balancing of the cost of heating surface against interest charges, and 1 square foot of heating surface can transmit heat (as demonstrated by existing locomotive boilers) at an approximate rate of 20,000 British thermal units per square foot per hour. With less efficient but more rapid transmission, twice this rate does not seem impossible. On this basis, apparatus capable of melting 100 cubic yards of snow an hour would require 500 square feet of heating surface. Certainly there is nothing abnormal involved in the provision of heating surface in such amounts as this.

One hundred cubic yards of compacted snow appears to be equivalent to about 450 cubic yards of snow as it falls, and in a 3-inch snowfall this amount would cover 500 linear feet of street. The subject obviously seems to be one that is worth consideration by the various cities in the country. It would be interesting to see some thoroughgoing experiments along this line.

The Protection of Iron and Steel by Paint Films*

By Norman A. Dubois

The theories of corrosion of iron and steel which have received consideration and which still seem to have their defenders and opposers are interesting to note. The carbonic acid theory in brief requires the presence of carbonic acid to start corrosion. The peroxide theory supposes that hydrogen peroxide is formed in the presence of moisture and oxygen, and that this hydrogen peroxide causes corrosion. The electrolytic theory assumes that iron passes into solution in water in the form of a ferrous ion before it can oxidize. A more or less complete discussion of these theories may be found in the various journals and other publications. It is not the purpose of this paper to discuss them.

From the standpoint of the paint technologist the problem is that of finding the paint film which will enable him to protect the exposed surface of iron and steel from the various rusting influences for the longest possible time. The theories of corrosion and numerous discussions of them have been of inestimable value, and the proper interpretation of them has enabled the paint technologist to improve his paint film. Let us briefly consider these theories from the standpoint in question.

The carbonic acid theory requires the presence of carbonic acid that corrosion may proceed. In other words, considering a paint film properly applied over the surface of iron and steel it requires that carbon dioxide shall pass through this film, and also that water, either as such or in the form of aqueous vapor, shall pass through the film, and there in conjunction with the carbon dioxide react as carbonic acid. The imperviousness of the paint film to carbon dioxide gas and to aqueous vapor, then, is the vital quality from the standpoint of this theory. The more impervious the paint film to the gases carbon dioxide and aqueous vapor, the longer it will protect the iron or steel from corrosion.

The peroxide theory requires the formation of hydrogen peroxide on the surface of the iron or steel. Considering a paint film properly applied over the surface of iron or steel, therefore, this means that the less pervious the paint film is to the gases oxygen and aqueous vapor, the smaller will be the quantity of hydrogen peroxide formed on the surface of the iron or steel, and the longer it will protect the iron or steel from corrosion.

The electrolytic theory requires that iron first pass into solution in water as ferrous ion, and that it is then acted upon by oxygen dissolved in the water or by carbon dioxide and water to form rust. Again considering a paint film properly applied over iron or steel this theory requires the presence of water in which the iron may dissolve to form ferrous ions. Obviously, the only way the water can get to the iron or steel is to pass through the paint film, as such, or in the form of aqueous vapor. If we suppose the ferrous ions have been formed, the action can go no further in the absence of an oxidizing agent, presumably oxygen, which in turn must get through the paint film. The reasoning for the presence of other gases is similar. We find, therefore, that for corrosion to proceed according to the electrolytic theory the gases, aqueous vapor, oxygen, or others must pass through the paint film, and, as in the other cases, the more impervious the paint film to gases and moisture, the longer it will protect the surface of the iron or steel from corrosion.

This is but to conclude that the paint film which will serve for the longest time as a protection to iron or steel against corrosion is the one which is the least pervious to aqueous vapor, the gases oxygen and carbon dioxide, or in fact any gas in the surrounding atmosphere which may in any way cause or accelerate corrosion.

If we assume the corrosion to be entirely due to the deterioration of the paint film rather than to its permeability to aqueous vapor and other gases, the same conclusion holds, as the rate of deterioration will be proportional to the permeability of the film to the deteriorating elements.

The electrolytic theory of corrosion has given rise to a division of pigments into three classes: corrosion accelerators, corrosion inhibitors, and inerts. While these pigments seem to give results as predicted by this theory in the presence of an abundance of water or when the iron or steel is actually immersed in water, it does not necessarily follow that they will do so, to a like extent at least, when incorporated in a paint film where conditions are much different.

Assume, for instance, that our paint film is somewhat pervious to aqueous vapor and other gases. It follows that just as much moisture may enter to the iron or steel surface and perhaps give conditions under which the electrolytic theory may apply when outside conditions are damp, this moisture may also pass from the steel surface outward when outside conditions are dry, and thus leave the steel surface dry, in which case the electrolytic theory cannot possibly apply. As a matter of fact, the actual conditions existing on the surface beneath the paint film, in most instances, are very probably between the two extremes of somewhat damp and nearly dry, and this is far from being covered with an abundance of water at all times, the conditions under which the electrolytic theory seems to work out well. This reasoning is borne out by the fact that a piece of bright steel immersed in water containing a little zinc chromate in suspension will remain bright perhaps indefinitely, while the same pigment in a paint film under ordinary conditions will not protect the steel in a like manner.

Again, two paints composed of the same vehicle, but the first containing a so-called corrosion accelerator only, painted on a steel surface in a locality of ordinary dryness will outlast to a great extent the second containing a rust inhibitive pigment painted on a steel surface in a locality habitually very damp.

This reasoning seems to indicate and the evidence seems to bear out the conclusion that the problem of iron and steel preservation is rather to be solved by making our paint film as nearly impervious to gases as possible than by trying to prevent corrosion by the addition of the so-called inhibitive pigments.

The problem is a physical one rather than a chemical one, and a comparison of paint films as to their relative obstruction to the diffusion of gases will tell more regarding their value as protection against corrosion than a study of the inhibitive action of their pigments. This is not to say that the inhibitive property of certain pigments is not worth consideration, but the imperviousness of the films is of far greater importance.

A New Passenger Ropeway

The methods of constructing ropeways have been so thoroughly perfected that large numbers have been built for the conveyance of both passengers and merchandise in various parts of the world and have proved entirely successful and satisfactory. A new installment that has recently been put into operation at Bozen, in Germany, is thus described: The way is 5,400 feet long, with a rise of 2,750 feet, the grade being an average inclination of 43 degrees. The up-and-down lines are located 20 feet apart and each consists of two steel cables, 20 inches apart, on which runs a four-wheel trolley. The cars, of which there are two, each with a capacity of sixteen people, half inside and half outside, are attached to these trolleys, and the two cars are connected by double cables operated by an electric motor located at the highest station. The current is derived from a central station, but there are batteries for use in an emergency, and hand gear is also fitted to the cars, one of which descends as the other ascends. This ropeway is supported on steel towers, the highest one being 50 feet, while the longest span between towers is 1,300 feet.

The Relation of the Horse-Power to the Kilowatt*

Reasons for the Adoption of an Absolute and Invariable Standard of Power

The value of the horse-power may be expressed either in gravitational or in absolute units of power. Confusion often results when one equivalent is reduced to the other since the gravitational units depend on the force of gravity which varies from place to place, and the absolute units do not. Thus the usual gravitational value for the English horse-power 550 foot-pounds per second, when reduced to watts gives a different number according to the value of the acceleration of gravity employed in the conversion, and hence we find different values in various reference books, of which the following may be cited:

	Watts
Kent's Mechanical Engineers' Pocketbook (1913) page 93	746
Suplee's Mechanical Engineer's Reference Book (1904) page 80	746
Standard Handbook for Electrical Engineers (1908) page [illegible] and (1910) page	745.6
Foster's Electrical Engineer's Pocketbook 1908	
Page 3	746
Page	745.650
Trautwine's Civil Engineers' Pocketbook 1911 page 44	745.956
American Civil Engineers' Pocketbook 1912	
Page 97	746
Page 13	745.7
Merriman's Conversion Tables (1904) page 8	745.650

Such confusion has arisen because there has been no accepted authoritative definition of the horse-power. When the horse-power is taken as a specified number of watts it represents the same amount of power at all places. But when the horse-power is taken as a specified number of foot-pounds per second the amount of power represented by it varies for different places. This is evident since the weight of a "pound" as a unit of force, varies in value as g, the acceleration of gravity, varies. Thus since g is greater for northern latitudes than for southern, the force represented by a definite number of pounds increases as one goes north. This makes this mode of definition of the horse-power very unsatisfactory. It is similar to a proposal once made to define the meter as the length of the seconds pendulum. No one would now consider seriously a unit of length which varies at different parts of the world. Nevertheless units of force having precisely that characteristic are in common use at the present time. The gravitational system of units centers about the gravitational unit of force and it is accordingly impossible to understand the subject without careful consideration of the pound and other gravitational units of force. For the attainment of precise numerical relations the value of g must also be carefully considered and authoritative data on this will be given below.

THE POUND AS A UNIT OF FORCE

The pound and the kilogramme are primarily units of mass. It is convenient to use the force of gravity upon masses to measure forces, so that units of the same names are used for force (or weight) as for mass. The inherence of the acceleration of gravity in these units of force is often forgotten and is the cause of some confusion. The pound as a unit of force has generally been used as a gravitational unit, the characteristic of the gravitational units being that their magnitudes vary with locality as g varies. Thus a pound force is equal to the force of gravity on a pound mass at any place where measurements happen to be made. The one advantage of the gravitational system is that a given mass exerts the same *number* of pounds of force no matter what its location. But by this mode of definition the *magnitude* of the pound force is not constant, as it varies with g. A few writers on the other hand have defined the pound force as a fixed unit, taking it as equal to the force of gravity on a pound mass at some one particular place—e. g. Paris or 45 degrees latitude and sea level—thus destroying the gravitational character of the unit.

The unit of force can be made definite and fixed, however, without abolishing the gravitational system. This is done by recognizing the difference between the absolute and the gravitational pound by the use of the terms "standard" and "local," respectively. The principle involved is that contained in the definition of "standard weight" by the International Conference on Weights and Measures in 1901. The statement[1] by the conference is given herewith:

The term weight designates a quantity of the same nature as a force; the weight of a body is the product of the mass of that body by the acceleration of gravity; in particular, the standard weight of a body is the product of the mass of that body by the standard acceleration of gravity.

The number adopted in the International Service of Weights and Measures for the value of the standard acceleration of gravity is 980.665 cubic centimeters per second.

By analogy with standard weight, the "standard pound force" may be defined as equal to the force of gravity on a pound mass at a place where g has the standard value 980.665 cubic centimeters per second per second or 32.1740 feet per second per second. Likewise the "local pound force" in any given locality may be defined as equal to the force of gravity on a pound mass in that given locality. Similar definitions apply to the terms "standard kilogramme force" and "local kilogramme force." In specifying a force in local units it is desirable to give the location of the place by such expressions, e. g. as "London pounds," "New York kilogrammes," "local kilogrammes (g=981.26)," etc. This application of the terms "standard" and "local" to the common units of force was proposed by Prof. E. V. Huntington of Harvard University and is followed in this circular.

The words "pound" and "kilogramme" used alone as units of force are ambiguous. When so used the local unit must usually be understood. This has been the usual sense of the terms as used in the past. Such an interpretation is clearly implied in the analogous statement on weight by the international conference above. Writers careful enough to use standard pounds or kilogrammes may be expected to use the word "standard" explicitly, while those who use "pound" without thinking how it is defined will naturally employ the local unit.

The terms here given are readily extended to derived units based upon the units of force. Thus definitions follow at once for "standard foot-pound," "local foot-pound," "standard kilogramme meter," etc.

THE VALUE OF THE ACCELERATION OF GRAVITY

The standard value of g, 980.665 cubic centimeters per second per second, was originally intended to represent the latitude of 45 degrees and sea level. It has been widely used as a standard value for barometric reductions, etc., since 1901, and there is no reason why it should not continue in use as a standard value, although the accepted theoretical value for 45 degrees and sea level is now a few parts in 100 000 different. The exact value obtained for 45 degrees and sea level varies with the gravity observations utilized and also with the theory adopted for the anomalies or departures of the observed values of gravity for any particular stations from the values calculated by a general formula. It is generally conceded to be better to retain a certain value as standard rather than to correct it from time to time to make it agree with a theoretical location. The value 980.665 is the result of a calculation made by the International Committee on Weights and Measures[2] from Defforges' absolute determination[3] of g at the International Bureau in 1888.

In calculating the equivalent of the horse-power in various units for different latitudes the following formula is used:

$$g=978.038\ (1+0.005\ 302\ \sin^2\phi-0.000\ 007\ \sin^2 2\phi)$$

where ϕ is the latitude. This formula[4] is accepted by the United States Coast and Geodetic Survey and is the result of observations all over the United States with Hayford's corrections for isostatic compensation. It is referred to the absolute determination of g at Potsdam about 1900. The theoretical values given by this formula will not in general agree exactly with the actual values at any particular place because of the local anomalies caused by topography, etc. The departures are in general only a few parts in 100,000. As this formula does not give g=980.665 for ϕ=45 degrees, the point is once more emphasized that 980.665 is an independent standard value not precisely related to a fixed locality.

PRACTICAL NEED FOR AN INVARIABLE UNIT OF POWER

Power is very commonly measured with considerable precision and hence it is important that the magnitude of the unit should not vary from place to place. From the standpoint of metrology the definition of any unit should be rigorous and free from ambiguity. The necessity for a precise definition exists at the present time in engineering practice. When extensive research is being made upon steam turbines when tests are made carefully and results are interpreted minutely there should be no uncertainty in the units used.

A precise definition is desirable even in the commerce of to-day. Misunderstandings might arise over the acceptance or rejection of an engine under test because of the definition of the unit of power. If the power delivered by the engine is measured by the use of a brake with weights, the number of foot-pounds per second observed would be greater, for example, at New Orleans than at New York, since the force exerted by the weights is different for different latitudes and altitudes. Consequently if the horse-power is defined as a definite number of foot-pounds per second the same at all places, it is possible that the engine might be accepted if the test were made at New Orleans and rejected if the test were made at New York. These remarks also apply to the case of testing an engine when the force is measured by a dynamometer or an indicator, as well as when measured directly by weights. If the springs were all standardized at the same place then the variation of the force of gravity would not enter the problem. However the elasticity of springs varies with temperature, etc., and hence in the making of an accurate test the spring is calibrated by weights at the time and place of the test. Consequently in any case the variation of the force of gravity with locality must be considered in interpreting the results of a test. The differences here discussed are less than 1 per cent and greater errors than this would be introduced in any practical case by variation in the lubrication, in the measurement of power and in the quality of steam. Nevertheless the mean of a series of tests would be taken as the performance of an engine and if this figure were just on the margin of tolerance an uncertain definition of the horse-power might cause misunderstandings. No such confusion is possible if the horse-power is defined in such a way as to always represent the same amount of power.

On account of the variation with g, and because the equivalents of the horse-power are not decimal multiples of any of the fundamental units and, further, because its definition and value are different on the Continent of Europe from its definition and value in England and America, it has long been felt that the horse-power is an unsuitable unit for many purposes. Modern engineering practice is constantly tending away from the horse-power and toward the watt and kilowatt. In Germany it has been proposed to call the kilowatt "Neupferd" (new horse-power) to make its use appeal more strongly to those who have become firmly attached to the horse-power. The objection to the horse-power has been particularly strong in electrical engineering. The International Congress of Electricians at Paris in 1889 recommended that the power of machines be expressed in kilowatts instead of in horse-power. A more definite and powerful action with a view to the elimination of the horse-power was taken by the International Electrotechnical Commission at Turin, Italy, in 1911. This body composed of the representatives of great electrical interests all over the world recommended that in all countries electrical machinery, including motors, be rated in kilowatts only.

HISTORICAL

The term horse-power as a measure of the activity of machinery was introduced[5] by Thomas Savery, the inventor of an early type of steam engine. The earliest application of the steam engine was in the pumping of water from mines, work which had formerly been done by horses. Savery in his *Miners' Friend*, page 29, in the year 1702, says that an engine which will raise as much water as 2 horses working continuously in a given number of hours will do the work or labor of about 10 horses, since relays of horses must be used to keep the work going continuously; such an engine then he called a 10-horse-power engine.

James Watt, who is generally known as the inventor of the modern steam engine, adopted[6] the term horse-power as a unit for expressing the power of his steam engine and defined its value in gravitational units, viz., foot-pounds per minute. The magnitude of Watt's horse-power was, however, six or eight times as great as Savery's. The value[7] was derived from experiments made under the direction of Watt and Boulton, his business partner, about the year 1775.

Some heavy horses of Barclay & Perkins's brewery, London, were caused to raise a weight from the bottom of a deep well by pulling horizontally on a rope passing over a pulley. It was found that a horse could raise a weight of 100 pounds while walking at the rate of 2.5 miles per hour. This is equivalent to 22,000 foot-pounds per minute. Watt added 50 per cent to this value, giving 33,000 foot-pounds per minute, or 550 foot-pounds per second. The addition of 50 per cent

TABLE 1

Various Values Adopted For The Horsepower

(Foot-Pounds Given in Terms of the Local Foot and Pound)

		Foot-pounds per second	English horse-power	Kilogramme-meters per second	Authority[8]
England and United States		550.	1.0000	76.041	V
Austria (old)		[illegible]	[illegible]	[illegible]	H
Switzerland		[illegible]	[illegible]	[illegible]	A
Sweden		[illegible]	[illegible]	[illegible]	H
Russia		[illegible]	[illegible]	[illegible]	H
Prussia		[illegible]	[illegible]	[illegible]	H
Saxony		[illegible]	[illegible]	[illegible]	H
Baden		[illegible]	[illegible]	[illegible]	H
Württemberg		[illegible]	[illegible]	[illegible]	H
Bavaria		[illegible]	[illegible]	[illegible]	K
Modern Germany, Austria, France, Italy, etc.		......	[illegible]	75.000	V

was an allowance made for friction, so that a purchaser of one of his engines might have no ground for complaint. The figure thus arrived at by Watt is admitted to be in excess of the power of an average horse for continuous work, and is probably at least twice the power of the average horse working six hours per day.

Since the time of Watt his value has been in general use in England and the United States, and 550 foot-pounds per second is known as the English horse-power. As the use of the steam engine spread from England into other countries the value of the horse-power was translated into the units of the various countries; that is, since the foot and pound had different values in the different countries, the number of foot-pounds in a horse-power necessarily varied. These values were given to the nearest round number, and hence the equivalence to the English horse-power was only approximate, the value averaging about 1 per cent smaller. Hence arose the discrepancies shown in Table I.

After the metric system had come into use in France, Germany and Austria the values of the horse-power in the various countries were reduced to kilogramme-meters per second, with the results shown in the table. The values range from 75 to 76 kilogramme-meters per second, averaging only a little more than 75. Hence, this round value, 75, has been adopted generally on the Continent as the value of the horse-power.

The English value, 550 foot-pounds per second, is, however, equivalent to 76.041 kilogramme-meters per second, and hence it is that there is a difference of nearly 1.5 per cent between the value generally used in English and American practice and that used in continental practice. Reduced to watts, the English horse-power is generally taken as 746 watts, although the precise equivalent, in watts, of 550 foot-pounds per second depends on the acceleration of gravity, and hence on the latitude and altitude. This is discussed fully below.

It is unfortunate that the value of the horse-power on the Continent of Europe was not taken as 76 kilogramme-meters per second instead of 75, in order that it might agree with the English value, as was originally intended. It is perhaps unlikely that a change to 76 could now be made, or that an agreement could be reached by which the continental and the English horse-power would correspond to the same number of watts. It is to some extent customary for continental writers to distinguish the two horse-powers by the words "English" and "metric." We shall call the latter the "continental horse-power." Thus, German writers speak of the "Englische Pferdestärke" and the "metrische Pferdestärke." The term "Pferdestärke" is now the preferred name for the horse-power in Germany, the old term "Pferdekraft" being unsuitable because "Kraft" means "force." Similarly, in France, the old term "force-de-cheval" has been given up for "cheval-vapeur." There is another unit of power which has been used in Europe, the "poncelet," or 100 kilogramme-meters per second. This unit was named in honor of Jean Victor Poncelet, who introduced the teaching of kinematics at the Sorbonne in 1838. This unit was adopted in France shortly before 1846, according to C. F. Peschel.[9] It was adopted as a unit of power in 1889 by the "Congrès international de méchanique appliquée." Its use is still permitted in the electrical regulations issued by the "Association alsacienne des Propriétaires d'Appareils a Vapeur." It has not, however, been much used in practice.[10] This is probably due in part to the fact that the horse-power had so firm a hold as the unit of power, and in part to the very near equivalence of the poncelet to the kilowatt. The poncelet is open to the same objection as the horse-power when the latter is rigidly defined as a certain number of foot-pounds or kilogramme-meters per second, viz., that the power it represents varies from place to place.

EQUIVALENTS OF THE ENGLISH AND AMERICAN HORSE-POWER.

It is possible to define the horse-power in such a way that the value determined by James Watt will be continued and yet the unit will represent *the same rate at all places*. The convenient and frequently used equivalent, 746 watts, happens to be equal to the rate of work expressed by 550 local foot-pounds per second *at 50 degrees latitude and sea level*, nearly the latitude of London, where Watt's original experiments to determine the horse-power were made. The horse-power is therefore taken to be equal to the definite amount of power, 746 watts, and in consequence the number of foot-pounds per second corresponding to 1 horse-power varies with the value of g. The number of standard[11] foot-pounds per second in a horse-power = 550.22. The same rate of work is expressed by a larger number of foot-pounds per second in lower latitudes and higher altitudes, where the force of gravity is less, and by a smaller number of foot-pounds per second in higher latitudes where the force of gravity is greater. Table 2 gives the number of foot-pounds per second in a horse-power at various latitudes and altitudes. The value of g at sea level is obtained from the formula previously given. The change with altitude is calculated from the correction to the value of g, viz., -0.000192 per meter elevation. The number given in the table for 45 degrees and sea level is 550.24; the fact that it differs from the number of "standard" foot-pounds per second, above, emphasizes again the fact that the standard value of g does not correspond quite exactly to 45 degrees and sea level.

TABLE 2

Value of the English and American Horsepower (746 Watts) in Local Foot-Pounds per Second at Various Latitudes and Altitudes[12]

Altitude	Latitude				
	0° (equator)	30°	45°	60°	90° (pole)
Sea level	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
5000 feet	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
10000 feet	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

The foregoing table may be put in the following approximate form for ease of remembering:

TABLE 3

English and American Horsepower (746 Watts) at Various Latitudes

Latitude	Local foot-pounds per second (approx.)
90°, pole	549
50°, London	550
(38°, Washington)	(550.5)
30°, New Orleans	551
0°, equator	552

The value of the English horse-power may also be given in metric units for various latitudes and altitudes, as follows:

TABLE 4

Value of the English and American Horsepower (746 Watts) in Local Kilogram-Meters per Second at Various Latitudes and Altitudes

Altitude	Latitude				
	0° (equator)	30°	45°	60°	90° (pole)
Sea level	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
1000 meters (=3300 feet approximately)	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
2000 meters (=6600 feet approximately)	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

By interpolation one can take out of these tables the proper value of the horse-power in gravitation measure (either foot-pounds or kilogramme-meters per second) for any latitude and altitude.

EQUIVALENTS OF THE CONTINENTAL HORSE-POWER.

The continental horse-power is generally given either as 75 kilogramme-meters per second or as 736 watts. These two equivalents are independent definitions and are likely to cause confusion *unless* one of them is assigned to some definite place on the earth's surface. As pointed out in the preceding sections of this circular, the unit, to be definite, should represent the same rate of work at all places. The continental horse-power, then, should be taken as 736 watts, which is equivalent to 75 local kilogramme-meters per second at latitude 52 degrees 30 minutes, or Berlin. The number of kilogramme-meters per second expressing this amount of power will be smaller than 75 at more northern latitudes and larger at lower latitudes. The values at various latitudes at sea level are given in Table 5:

TABLE 5

Continental Horsepower (736 Watts) in Local Kilogram-Meters per Second

Altitude	Latitude				
	0° (equator)	30°	45°	60°	90° (pole)
Sea level	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
1000 meters	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
2000 meters	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

[11] As explained in Sec. II, the standard foot-pound is that corresponding to g=980.665.

[12] The values given in these tables supersede those given in the first edition of this circular, which were calculated from a slightly different value of g. The equivalent used in this circular for the horse-power also supersedes that used in editions of this Bureau's "Tables of Equivalents" before 1913.

CONCLUSIONS.

It is considered desirable that the watt and kilowatt be used as the units of power, whenever possible, for all kinds of scientific, engineering, and other work. It is not unlikely that the unit of horse-power will ultimately go out of use. In the meantime, however, it is desirable that its definition be uniform. This circular has been written to point out that if the horse-power is to represent *the same amount of power at different places* its relation to the watt must be a constant number, and the number of local foot-pounds or kilogramme-meters per second which it represents must vary from place to place. Table 2 and others of this circular show clearly this variation with locality.

It might be feared that some confusion could arise because of the independent definitions of the mechanical watt and the "international" electrical watt. The watt and kilowatt are defined primarily in purely mechanical terms, and not electrically at all. That they have been used mainly in electro-technical work is merely accidental and is due to the fact that they are metric units and so fit in naturally with the metric units in which all electrical quantities are universally expressed. Any kind of power may properly be measured in kilowatts. For example, in the case of the hydraulic power furnished by a flowing stream, the power is given in kilowatts by multiplying 0.163 into the product of the head in meters by the flow in cubic meters per minute; the power is likewise given in kilowatts by multiplying 0.000188 into the product of the head in feet by the flow in gallons per minute. The watt is defined directly in terms of the fundamental units of mass, length, and time, in the "meter-kilogramme-second" system, thus: "The watt is the power developed by the action, with a velocity of 1 meter per second, of a force capable of giving to a mass of 1 kilogramme in one second a velocity of 1 meter per second." The "international watt," however, is defined in terms of concrete electrical standards, which electrical standards represent practically, as nearly as the limitations of experiment allow, the absolute electrical quantities in terms of their theoretical relations to length, mass, and time. The international watt thus defined is the closest concrete realization of the theoretical absolute or mechanical watt which we have. We can not at the present time say whether the international watt is greater or less than the absolute or mechanical watt, but the difference is probably not greater than a few parts in 10,000. Consequently, there is in reality no confusion between the mechanical watt and the international electrical watt.

It is recommended that engineering societies and other interests concerned recognize the value of the "English and American horse-power" as 746 watts (or 550 foot-pounds per second at 50 degrees latitude and sea level, approximately the latitude of London), employing Table 2 to obtain the value in foot-pounds per second at other places. It is likewise recommended that the value of the "continental horse-power" be taken uniformly as 736 watts (or 75 kilogramme-meters per second at latitude 52 degrees 30 minutes, the latitude of Berlin), and that the value in kilogramme-meters per second at other places be obtained from such a table as Table 5 of this circular.

It is probably not generally known that those values were adopted by a committee of the British Association for the Advancement of Science in 1873. This was a committee which recommended the cgs system, and on it were Sir W. Thomson, Carey Foster, Clerk Maxwell, J. D. Everett, and others (B. A. Report 1873, p. 222). The committee in its report said: "One horse-power is about three-fourths of an erg-ten per second. More nearly, it is 7.46 erg-nines per second, and one force-de-cheval is 7.36 erg-nines per second." (One erg-nine = 100 watts).

The Standards Committee of the American Institute of Electrical Engineers adopted, on May 16th, 1911, the following rule, which was inserted in the Standardization Rules of the Institute:

"In view of the fact that a horse-power defined as 550 foot-pounds per second represents a power which varies slightly with the latitude and altitude (from 743.3 to 747.6 watts), and also in view of the fact that different authorities differ as to the precise value of the horse-power in watts, the standards committee has adopted 746 watts as the value of the horse-power. The number of foot-pounds per second to be taken as 1 horse-power is, therefore, such a value at any given place as is equivalent to 746 watts; the number varies from 552 to 549 foot-pounds per second, being 550 at 50 degrees latitude (London), and 550.5 at Washington. The Standards Committee, however, recommends that the kilowatt instead of the horse-power be used generally as the unit of power."

The same value, 746 watts, is used by the Bureau of Standards as the exact equivalent of the English and American horse-power. The Bureau recommends the use, whenever possible, of the kilowatt instead of the horse-power.

The Rural School and the Hookworm Disease*

The Greatest Medium for the Spread of the Infection and the Most Important Protective Agency

IN the last third of a century education in the United States and particularly in the Southern States where the preponderance of rural population has retarded community control of sanitation realization of the health basis of education has been slow. Education in the south has advanced rapidly since the Civil War and more recently the rural schools have had their share in progress. Yet in this development the emphasis has persistently been on the school and the teacher rather than on the children to be educated. Only recently have educators turned their attention to the physical condition of the average school child and in the south they have done so largely because of the discovery of the enormously important part played by hookworm and allied diseases in educational progress or lack of progress. Hookworm disease is in a sense a special problem but it is a special problem of such magnitude affecting so large a section of our country as to be a problem of grave national concern.

Hookworm disease is one of the most prevalent most insidiously harmful and most completely preventable diseases known to man. It causes human suffering and economic waste altogether out of proportion to its apparent death rate. Many ills that have been attributed to mental and moral weakness of whole bodies of people are now definitely known to be due to this infection and curable with its cure. Its eradication is one of the most important and pressing problems before the people of the southern half of the United States and of other semitropical and tropical lands. Moreover the progress which has been made in recent years completely demonstrates at once the vast benefit both in terms of human happiness and industrial efficiency attendant on the stamping out of the disease and also the complete adequacy in stamping it out of perfectly simple precautions prescribed by the most primary rules of health and even of common decency. There is probably no other disease which is so well understood in every detail and which can be so satisfactorily explained to a layman. Nor is there any other widely prevalent disease against which the lay community can so readily and surely protect itself by simple precautions. Its conquest virtually resolves itself into a problem of popular education against soil pollution.

In combating hookworm disease it has been found that the rural school is the greatest medium for the spread of the infection and the most important protective agency against it. In some schools investigated the infection has been found to be 100 per cent—the teacher and every pupil a victim of the disease. Records of the survey show an average infection among rural children of school age for whole counties running as high as 70 to 90 per cent. The general average for all the children examined to date is 40 per cent of infection.

It is seldom realized to what extent the school in rural districts aids in spreading the infection. Suppose we take a certain school district in which by chance no infection exists. The son and daughter of Mr Smith visit Mr Jones who lives in a district where there is much hookworm disease. While there fruits or strawberries are picked off the ground by the Smiths and eaten and perhaps in going barefooted ground itch the beginning of skin infection is contracted. The visit over the Smiths return home. Having no sanitary privy on their premises the soil around their home is soon polluted so that one by one the whole family becomes infected in varying degrees of severity. Fall comes and the neighborhood school opens. The Smith children may by this time be a little pale and puny from the disease but they start to school.

The school may be in a progressive community: the house may be painted and furnished with patent desks and perhaps it has secured a creditable library. Good heaters have been provided; the light comes from the rear and over the left shoulders of the pupils; perhaps there is a driven well to supply water but there will be no bubbling drinking fountain. Worst of all no privy has been provided. The pupils not having a privy at home do not think of having one at school especially since the woods and undergrowth are near the school house. The Smith children do not know they are infected; they use the common hiding grounds with the other children. Soon the whole school grounds are so heavily polluted that on damp days every pupil who goes around barefooted will contract ground itch; and moreover those who play ball, marbles, mumble-the-peg, etc., get their hands infected. Facilities for washing the hands are not available so at lunch time they handle their food with soiled hands which are likely to be contaminated.

In this way the pupils at school become infected with the school as an exchange. In a comparatively short time the premises around the homes of all the school children are polluted and we have the change which anemia produces coming over the community. Progress of the children in school is retarded; the daily attendance is poor; the health of the community is below normal; the crops are not so well cultivated; there is a general backward tendency. The houses are not so well provided for or kept; the whole community is sick and doesn't know it; the economic loss is tremendous.

It is through the rural school whence the infection has come that the remedy must also come. The measures necessary for permanent control of hookworm disease are health supervision, health instruction and perfect sanitation. The rural school can aid in health supervision; it can supplement and drive home health instruction; and above all it can teach good health and clean living by being itself a model of sanitation for the community.

Hookworm disease like typhoid fever is due to careless disposal of human excreta. Once schools and dwellings in country districts are provided with sanitary privies of one type or another there will be little danger from hookworm.

Infection by intestinal parasites is by no means confined to the south. It is world wide in its distribution. It is most prevalent in the tropical and semi tropical countries where it is a problem of great magnitude. Of the total population of the globe—about 1 600 000 000 people in round numbers—about 940 000,000 live in countries where hookworm disease is prevalent. In the microscopic examinations of the stools of persons six types of intestinal parasites have been found in sufficient frequency to render each one worthy of consideration, but the campaign in the south has been directed primarily against the hookworm because it is the most important, and by far the most prevalent of the group.

Hookworm disease is not new. It is only newly understood. The symptoms of the disease were described in the records of the Egyptian Empire, but their cause was not known. The hookworm itself was discovered in 1838 by Dr Angelo Dubini, an Italian, who while making an autopsy found the small white worm with its head buried in the membrane of the small intestine, but that this worm had anything to do with anemia was not suggested. When, however, in 1877, Grassi another Italian physician identified the eggs of this worm in the feces of anemic patients, it was suspected that the parasite was the cause of the disease. About the same time Dr Colomiatti studying an obscure disease which had caused the death of many workmen on the St. Gothard Tunnel, discovered in the intestine of one of the tunnel victims more than 1,500 hookworms.

This parasite known as the Old World hookworm and named *Ankylostoma duodenale* was carefully studied its responsibility for certain types of anemia in southern Europe demonstrated, and successful treatment for the disease developed. The prevalence of hookworm disease in the New World was not, however, recognized till much later. On November 24th, 1899 Maj Bailey K Ashford of the United States Army Medical Corps, while treating anemia supposedly due to starvation caused by the hurricane in Porto Rico identified the hookworm as the real cause of the widespread disease. He however supposed the parasite found by him to be the Old World type. In 1902 Dr C W Stiles, of the United States Public Health Service, having found the same disease in the southern states identified its cause as a different species of worm now known as the New World type or *Necator Americans*. It was then discovered that the worm found in Porto Rico was of this species. Subsequent discovery of this same worm as the cause of anemia among the victims of the African low lands suggests that the so-called New World type was brought to Porto Rico and the southern states by the slave trade. It also prevails in India, and has been spread in Jamaica, Trinidad and British Guiana by the Hindu coolies brought there as laborers.

In the United States the disease is found throughout the states south of the Potomac and Ohio Rivers in Arkansas, Missouri, Oklahoma, and Texas and also in California. Its prevalence and severity vary widely within a state and even in a county. In some localities less than 1 per cent of the people being infected, and in others more than 90 per cent. Generally speaking the heaviest infection is found on the light sandy soil of the coastal plains, the lightest infection on the stiff, clay soil of the Piedmont region, and an intermediate infection among the foothills and mountains. It is peculiarly a disease of the agricultural districts, which goes far to explain the long puzzling lack of physical and intellectual vigor to be noted among large classes of people in what ought to be one of the healthiest and most prosperous sections of the country.

The treatment of hookworm disease is a simple matter. Epsom salts and thymol are the drugs used. The object desired is to clean the mucous and food particles from the intestinal tract, so that the worms will be exposed to the action of the thymol. This is accomplished by the administration at night of a dose of Epsom salts. The next morning at 6 A. M. one-half the dose of thymol in capsules is given, at 8 A. M. the other half is given, and at 10 A. M. a second dose of Epsom salts is given. Having cleaned the mucous from around the worms, the thymol acts directly on them as a poison.

Alcohol and oils are solvents for thymol, and it is exceedingly dangerous for either of these to be taken by the patient. Gravy, butter, milk, etc., must not be taken on days when thymol is given. Patent medicines contain alcohol, and must be forbidden. The plan followed has been to forbid any food or drink, except water, on the morning when the thymol is taken.

Male fern, beta-naphthol, and other chemicals have also been used in treating hookworm disease, but it is generally agreed that thymol is thoroughly satisfactory for the purpose.

An Arkansas dispensary

Microscopist on field work in Georgia

*Extracts from Bulletin No 20 1914 issued by the U S Bureau of Education.

In the fall of 1909 it was announced that Mr. John D. Rockefeller had given a million dollars to be used in an effort to control hookworm disease. In January 1910, a commission composed of educators, doctors and business men of national reputation was formed and offices were opened in Washington by the administrative secretary. The work of this commission, which is known as the Rockefeller Sanitary Commission, has involved three definite tasks (1) To determine the geographical distribution of the infection and to make a reliable estimate of the degree of infection for each infected area; (2) to cure present sufferers; and (3) to remove the source of infection by stopping soil pollution.

The State was adopted as the unit of organization and of work. It was regarded as fundamental, in the interest both of economy and efficiency, that the work be done as far as possible through existing agencies. Each State had its own system of public health, its own system of organized medicine, its own organized public press, its own system of public schools. These four fundamentals and a host of other agencies were ready for use in educating the people. These institutions were rooted in the life and traditions of the people, to enlist these agencies in the accomplishment of the task was to insure the permanency of the work from the beginning. The eradication of this disease, moreover, was a work which no outside agency working independently could do for the people if it would, and one which no outside agency should do if it could. It was recognized that an outside agency can be helpful only in so far as it aids the States in organizing and bringing into activity their own forces. In this spirit the commission responded to invitations from State boards of health to co-operate in organizing the work in those States in which widespread infection had been demonstrated.

In the 11 States thus inviting co-operation a State director of sanitation was appointed by the joint action of the State public-health authorities and the Rockefeller Sanitary Commission. The State director is a State official, an officer of the State department of health clothed with all the powers and responsibilities belonging to such position. He is the organizing and directing head of the whole work for the eradication of hookworm disease in his State and is responsible for the efficiency of the service. His work is done under the supervision of the State department of health, he reports quarterly to the State department and the commission ¶

Under the direct supervision of each State director of sanitation is a force of field directors of sanitation. These field inspectors are nominated by the State director and confirmed by the joint action of the State department of health and the commission. These inspectors constitute an ambulant service and devote their whole time to work in the field. It is these field directors who determine the geographical distribution and degree of infection, who determine the sanitary conditions responsible for the presence and spread of the disease. They enlist the co-operation of the physicians in curing the sufferers, provide for the treatment of the indigent, inspect schools, instruct the teachers, enlist the press, and, by lectures, demonstrations, and personal conference, teach the people the importance of getting all infected persons cured and how to prevent the spread of the disease by putting a stop to soil pollution.

As a definite diagnosis of hookworm disease requires a microscopic examination of the patient's stool each State has a force of trained microscopists whose whole time is given to the examination of specimens received. This microscopic force is stationed at the State laboratory and in the field, in the latter case working with the field director.

The most effective teaching, whether of physicians, of editors, of school officials and teachers, or of the people, is by demonstration. The chief agency in this demonstration teaching has been the county dispensary for the free examination and treatment of the people. For this dispensary the county board of supervisors makes a small appropriation. The work is done by the field staff of the State board of health. The dispensary in a county runs usually from 6 to 8 weeks.

To summarize briefly, the aim of the work has been

1. To demonstrate to the people in each of the 11 States where work has been undertaken that hookworm disease is a reality; that it is a serious handicap, and that it is curable and preventable.

2. To make an infection survey that will give a reliable estimate of the degree of infection for each county in the State.

3. To make a sanitary survey which shall show for each county in the State the conditions of soil pollution which are responsible for the presence and spread of the infection.

4. To conduct an intensive educational campaign in every county where the infection is present; to teach the [illegible] of the printed page, by lectures, by [illegible], the importance to the [illegible] of [illegible] every person examined and the [illegible] how the examination is made; how the disease is treated, how the infection is spread, and how it can be prevented.

5. To teach the practicing physicians of the State how to diagnose the disease and how to treat it; to teach them the importance of making examination for intestinal parasites a regular part of routine examination of all patients.

6. To get every medical school in the State to make provision for definite instruction in the diagnosis and treatment of intestinal parasites to be given to all students as a requirement for graduation.

7. To enlist the press of the State in the work.

8. To see that the teaching of the dangers of soil pollution and how to prevent soil pollution is made a regular part of the instruction given in the public schools.

9. To make at least one complete community demonstration, to select a rural community where the infection is reasonably heavy to get every person examined, get every infected person cured, get soil pollution stopped, then tell the people of the State the story of how this community has eradicated hookworm disease.

10. And, if possible, to help lay the foundation of a county and community health service that will in the end take care of hookworm infection and all other preventable diseases.

Recently measures have been taken where the dispensaries have done their work thoroughly to follow the next logical step in the direction of permanent control of health conditions. In North Carolina the State board of health has secured for a number of counties and communities full-time health officers who in addition to fighting hookworm disease will do other needed health work. Instead of selecting a county and spending a short time there—the dispensary method—the board now has full-time men employed who can remain until every case of hookworm disease is treated and cured. In addition to this sanitary arrangements are being instituted for every home in the community, with a view to preventing hookworm disease, typhoid fever and all other diseases due to soil pollution.

Co-operation between the State departments of health and education has been one of the most hopeful signs of progress in the movement for community control of health conditions. In no field has this co-operation been more practical or effective than in the work for the eradication of hookworm disease. The school authorities have furthered in every way possible the efforts of the State health authorities in the various steps of survey, cure, and prevention.

In some of the States notably Virginia, North Carolina, Alabama, and Kentucky the alliance has been particularly close. The State health authorities have furnished bulletins on public health especially adapted to use in the schools and the State school authorities have distributed these bulletins of information to all the schools in the States.

Alabama has a specially prepared teacher's bulletin for use in the schools of the State, with an introductory note by the State director of campaign against the hookworm disease in the State.

Kentucky is another State where special bulletins on health subjects have been prepared by the State board of health at the express request of the State educational authorities.

In Arkansas State Supt George B Cook reports that the State department of public instruction has been very closely identified with the work of the Rockefeller Sanitary Commission since the work was first taken up in that State and that his department is also co-operating to the fullest extent with the State board of health.

Kansas, while not one of the States where hookworm disease is a problem offers a good example of State wide health teaching in country schools. In the new course of study issued for use in all the rural schools of the State, special stress is laid upon sanitation and health-conserving agencies in general.

In reporting on health teaching in Louisiana State Supt Harris mentions particularly the work of the State board of health in co-operation with the Rockefeller Sanitary Commission, emphasizing the fact that while engaged in the work of examining and treating school children and teachers "they give a great deal of instruction in other lines of health."

In Mississippi a valuable health work that means much for the hookworm crusade as well as for every other positive movement for good health is the work of the State school improvement associations. By means of these associations, working through the State department of education, a special "clean-up and beautify day" has been observed by at least 2,000 schools and communities at the close of school in the spring and again at the opening in the fall. On these days the country people join with the teacher to put their schools in sanitary condition and make them as attractive as possible.

It is the general testimony of those who have investigated actual rural conditions that the rural school is ordinarily inferior in building and equipment to the average farm dwelling of the community it serves. Certainly in respect to sanitary facilities it has been a disgrace to American civilization. Recently, however, much has been done toward making the school house and grounds in the country what they should ever be—a real model for the community to follow. In States where the rural movement is at its best particular attention is paid to the two fundamentals of water supply and sanitary privies.

No problem is of more fundamental importance to rural life than that of disposing adequately of human excrement. It has been repeatedly stated in this bulletin that hookworm disease would be impossible without soil pollution and soil pollution is directly due to the lack of sanitary privies. Theoretically the remedy for soil pollution is simple and should be provided with enthusiasm everywhere in the country at every farmhouse and at every school. Practically its application is very difficult. Ingrained habits must be changed and to accomplish this requires that people be educated out of the present uncivilized custom to the point where they will gladly devote the necessary time and money for the construction and use of sanitary facilities for night-soil disposal in other words sanitary privies.

Model Target Ranges in Belgium

A few years ago the Belgian military engineering corps undertook some interesting work in reinforced concrete construction at the time of laying out the new rifle ranges at Ostend. This locality is now covered by the present war operations in Belgium. The firing grounds were intended to be a model establishment and a novel point was the extensive use of firing walls or backing for the targets built of reinforced concrete and ranging from 30 to 70 feet high. Such a system had already been put in use in Switzerland and other places to a limited extent and owing to the valuable qualities of reinforced concrete for this class of work it was decided to go into the present construction on a much larger scale than had been heretofore seen. Plans for the complete firing ground at Ostend called for four firing lines at 330 feet range four lines at 660 feet, five at 1 000 feet four at 1 330 feet three at 1 650 feet and two at 2 000 feet range this being as will be seen quite an extensive layout all these firing lines to be provided with electro-automatic targets of the Bremer type which give an automatic record of the firing points. However only a part of this programme was carried out during the first part of the work to which our obtainable information has reference. In the same way the shelter for the firing men is temporarily built of wood lined with canvas in order to deaden the sound. The flooring of this shed construction is built on piles so as to raise it some 15 feet above the ground level. The plans call for a total length of 770 feet for this part of the work. Provision is also made for pistol firing as well as for combined firing by squads and other operations. Taking the case of the 1 000 foot range as an example the firing walls placed opposite the stand and holding the targets are built as five separate walls with space between. Such walls are of flat surface in front except for various niches to hold the targets as well as suitable protecting parts of which the details are not given. The wall has about 7 inch thickness in itself but is greatly reinforced by webs in the shape of buttresses in the rear which start flush with the wall at the top and slant to the base so as to project no less than 10 feet or more at the ground level. The walls vary in length and are either square or oblong shape the buttresses on each of the walls being spaced at reasonably close intervals for instance five of them per wall in some cases. Metallic web reinforcing on the French Hennebique system is used here and the surfaces which lie above ground receive an outer coating of cement mortar. The present walls are calculated to stand a much higher wind pressure than the heaviest tempests could produce and are thus very safe in this respect the broad base giving all the stability needed. For the 1 000-foot firing line the heights of the walls range from 30 feet to 75 feet.

Experience shows that reinforced concrete walls of this kind receive but little damage from the bullets but in the Ostend construction the walls themselves are protected by mattresses consisting of 1½ inch planking spaced at 8 inches in front of the surface of the wall then filling in the space with broken porphyry fragments of 1½ to 2 inches in size. In France such planking and filling is used alone for making up a back wall for firing grounds and it is found that the shot will not penetrate it in any case so that the Ostend construction has an extra margin of safety. Suitable precautions have also been taken to prevent glancing of the bullets from the targets or the walls. On the whole the present layout is a model one of its kind and shows another useful application of reinforced concrete. It is not stated what has become of the firing grounds since the war operations about Ostend.

The Defense of Belgium by Inundation

Something of the History and Geography of the Flooded Region

By P Sallior

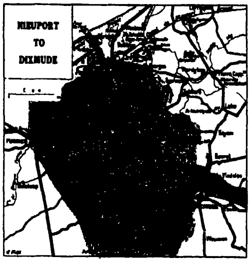
In all ages the regions bordering on the North Sea have made use of inundations as a means of defense. After having worked for centuries to wrest land from the sea by artificial agencies Belgium and Holland claim the right of returning for the moment to the waters the territories which they have won from them. During the siege of Antwerp it proved impossible for the district that could be submerged to yield the desired results. During the battle of the Yser however the zone of Nieuport and Dixmude found inundation a valuable means of resistance. While the war-ships of the Allies drew near the coast to bombard the Germans and batteries of artillery rained shells upon the district the lock gates were raised the dikes broken down at the right moment and the water flowed again over the land entering the trenches of the enemy and thus any farther progress of the Germans was rendered impossible.

An interesting account of this heroic undertaking is given by a writer in *La Nature* who describes this entire section of Belgium as a charming region filled with sleepy old towns redolent of the past possessing belfries markets old houses and peaceful convents of Beguines having bridges across the canals accustomed to quiet and tranquillity. It was customary for travelers to go to Nieuport to see the memorials of daring seamen and the surroundings of an old seaport to Dixmude to inspect the roodloft of the church and the town hall to Ypres to see the wonderful market-building and the belfry. Along the coast there were sandy beaches at Nieuport Middelkerke Mariakerke Ostend and Blankenberghe where children were wont to play.

One day continues our author the swarms of an adversary fell upon this region the cities of which are no longer more than names on the map or heaps of ruins. The foe had two aims in view to drive back the left wing of the Allies in order to resume its unending turning movement and also to advance by way of Furnes to the capture of Dunkirk which once in its hands would become a base for naval operations against England. Toward the middle of October this attack by the enemy was begun in the region between Nieuport and La Bassée and the operations were particularly violent at the outset along the coast. The Yser River which has been turned into a canal makes a long bend between Nieuport and Dixmude and during several weeks its banks were the scene of a violent struggle. The Belgians very quickly comprehended the aid which the water could give them. There were fine locks at Nieuport that Baedeker had advised his compatriots to go see as masterpieces especially the locks of the canals of Bruges and Furnes as well as four others that are noted on the accompanying map. Successive use was made of these locks and thus it was that the German attacks were progressively forced back from the lower courses of the river to the upper in proportion as the waters rose and encroached upon the land on the left bank of the canal. Up to October 21st the most severe attacks of the foe were at Nieuport and Lombartzyde. On October 22nd when the waters reached Schoorbakke the troops of the enemy forced a passage for themselves at Tervaete but were stopped three kilometers farther on at the railway line near Pervyse where one thousand dead Germans were found after a battle. On November 11th however a success at last threw into their hands temporarily the ruins of Dixmude which had already been taken and retaken several times but even this advantage did not enable them to gain the left bank of the Yser. By the end of November thanks to the aid of higher tides the inundations had extended over so large a region that the great German effort in which more than 120 000 men are said to have fallen had to be abandoned and the attacks reported after this were in a more southerly direction towards Ypres. The water has been seen extending from Nieuport to the immediate vicinity of Ypres flowing in its course through Schoore Leke Dixmude Bixschoote and Boesinghe. One result has been the capture of heavy artillery sunk in the miry ground near Ramscapelle where four large cannon and two mortars were gathered up out of the mud.

The present war is by no means the first time that this district has served as a battlefield. In 1489 Nieuport was besieged by the French. In 1600 Maurice of Orange won a victory there over the Spanish and in 1658 the Battle of the Dunes was fought not far from Nieuport in the direction of Dunkirk when Turenne defeated Prince de Condé and the Spaniards during the course of a campaign not so dissimilar in its happenings to the events that have just taken place.

At the period of this battle it should be recalled the French and the English were allied as at the present time. The forces of the enemy held Gravelines Dunkirk Bergues and Furnes. The entire region around Dunkirk had been inundated by them. Notwithstanding this Turenne marched boldly from Cassel to Bergues and following from the latter place the only practicable dike he reached the dunes with the intention of besieging Dunkirk. At this moment Condé who had collected at Ypres the Spanish garrisons advanced to meet him and was defeated June 14th 1658. Eleven days later Dunkirk capitulated. This was followed by the capture of Bergues Furnes and Dixmude which was taken July 4th Gravelines surrendered on August 30th and on September 26th Turenne entered Ypres.



Map of the inundated Yser region

In explaining the physical and hydraulic conditions of the region which permit this method of defense the writer says further

If a topographical map or what is better a map of the geological strata of this district is examined it will be seen that a line of dunes runs along the coast from Gravelines to Dunkirk Furnes and Nieuport. These dunes are united into a monotonous plain only broken by the slight elevation near Bergues or Hondschoote of older alluvial formations and thick beds of a clay called Flanders clay (of the stratified formation called Ypresian) which varies from a thickness of 140 meters at Ostend to 80 meters at Dunkirk.

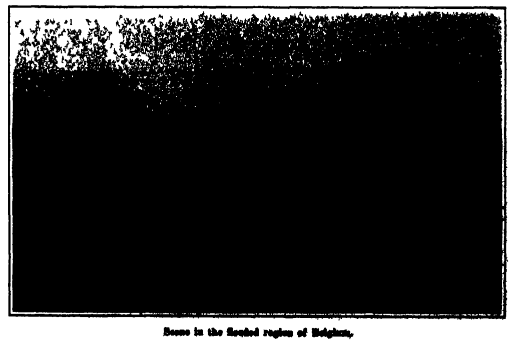
In traversing this country starting from the coast there first appears a low sandy shore a large expanse of which is exposed at each turn of the tide. Then when a northwest wind blows the sand is pushed toward the coast dunes are formed and always owing to the same influence these dunes advance inland while the sea attacks them behind. East of Dunkirk the dunes move forward more than 3 meters a year. It is the region of the leaden-hued landscapes which the painter Cazin loved to use as a background for Palestinian scenes. The strip along the coast formed by these dunes is only broken by the mouths of streams of small importance. These river-mouths are habitually shut by lock-gates that are only opened at low tide when their discharge can take place.

The plain back of the dunes is composed of a clay, whitish from the admixture of sea-shells at times a peaty subsoil is found below this clay. A layer of peat, which is often a meter thick underlies this clay at about the meridian of Dunkirk. Broken and recumbent trees are scattered irregularly through these strata. Innumerable canals and their subdivisions wind through this clayey plain which contains many stretches of verdant reclaimed land.

The entire region has been wrested foot by foot from the sea and is like the Netherlands, of which it is a continuation a marvel of human ingenuity.

The general level of the plain is in fact 0.60 meter below high water and in certain depressions called moeres it falls to 1.60 meter below high water. In order to form the polders or tracts of reclaimed land it has been necessary to shut off the sea gradually by dikes crossed by drainage canals and to establish gates to regulate the flow of the water by preventing its discharge excepting at low tides. Although this work of conquest was begun many centuries ago there still existed at the beginning of the 16th century a large number of salt lakes which have been drained off one after the other the moeres during the 17th century the salt-lakes of Lannes Robelin and Taaf during the 18th century.

It is consequently very easy says the writer in summing up to understand the method of defense that has been employed. In ordinary times the gates are closed when the sea rises. If the procedure is reversed the rising tide penetrates the region by means of the entire complicated network of canals shown on the map and the closed gates will prevent it from flowing off while retaining also the fresh water. If a person knows how to make use of the highest tides more than a meter in height over the level of mean tide can be gained. By breaking the dikes at suitable points one or another section of the country can be inundated as the embankments of a railway or of a road forming a dam. The ability to use the locks is a fine art but the low districts of Belgium have like the Dutch old experts who have been trained by long experience and who know all the tricks of the trade. It is said that the combination by means of which the German trenches were submerged while the Belgian trenches were protected for a sufficient length of time is due to one of these men. The map shows the extent of country liable to inundation, which includes almost the entire triangle of Dixmude Nieuport and Furnes. To the east and south of Dixmude the sands and clays of the Ypresian period are on a little higher level which protects them from the invasion of the sea. The Germans have tried in vain to stop the inundation or to cross over it by means of rafts. They have been compelled to seek another route with little success.



Scene in the flooded region of Belgium.

Deformation of the Earth by the Moon*

Methods of Solving the Problem and Its Difficulties

By Otto Klotz

IN chapter VI of "The Tides" by Sir George Darwin he discusses the deflection of the vertical by the tide-generating force of the moon. In 1879 in conjunction with his brother Horace, he attempted to measure the microscopic movement of a pendulum under the influence of the lunar attraction. The difficulties encountered "led us to abandon our attempted measurement and to conclude that all endeavors in that direction were doomed to remain forever fruitless. I can but hope that a falsification of our forecast by M. Ehlert and by others may be confirmed." This is the concluding paragraph in that chapter and the forecast as we know has been disproved first by the observation of Hecker, later by Orlov, Michelson and others.

If the earth were perfectly plastic then there would be no oceanic tides relative to the land for both would be deformed equally and tide gages would record no rising or falling of the water. Otherwise, if the earth were perfectly rigid then we would have the greatest effect of oceanic tides by the lunar attraction. As the earth occupies a condition intermediate between perfect plasticity and perfect rigidity, the ocean tides are considerably modified thereby. Darwin gives the intensity of the maximum horizontal force due to the moon compared with gravity as 1 to 11 660 000. As is seen this is a very small quantity and the difficulty of observing or determining it is manifest.

We will attempt to give an elementary exposition of observing the effect of lunar attraction in the solid earth by means of the horizontal pendulum and evaluating the recorded results. In outline the horizontal pendulum is simply a bob supported at one end of a horizontal boom the other end being movable at a steel point resting in an agate cup while fine wires support the bob from a point on a vertical rod. Now this latter point is not quite vertically above the lower point and therein lies the merit of the horizontal pendulum. If the axis of rotation were vertical then the pendulum would not oscillate when displaced from any position it might occupy. However as soon as this axis is inclined to the bob the pendulum will oscillate when displaced from its zero position and the period of its oscillation that is the time required to make a to-and-fro movement will be dependent upon this inclination of the axis. The period is a function of the angle of inclination to the vertical. This angle is a matter of instrumental adjustment, so that we can give the pendulum a definite period of oscillation to suit our purpose of investigation. If for instance its period is 10 seconds for a single vibration this would be equivalent to an ordinary pendulum hanging vertically as in a clock of approximately 100 meters in length or say 330 feet. Expressed in this manner one sees what a very small force indeed would be required to deflect the latter pendulum from its vertical position. Now this deflection we could accomplish too by tilting the support on which the pendulum hangs that is if the surface of the earth suffered a tilting or inclination to the horizontal the vertical pendulum would move through the same angular measure, and the longer the pendulum the more easily could we measure the linear displacement. With the above equivalent 100-meter pendulum we would have a maximum deflection of the 11,660 000th part or a little less than one hundredth of a millimeter. Knowing the mass and distance of the moon as well as the intensity of gravity it is a simple mathematical problem to calculate the deflection of the vertical at any time for a rigid earth.

The physical tides of the earth follow the apparent motion of the moon, and hence the deflection of the pendulum has a to-and-fro movement under the lunar attraction twice a day and with far greater regularity than obtains with the ocean tides, which are impeded in their onward course by the configuration of the earth's surface, i. e., by the continents.

We are speaking only of the lunar attraction while there is, too, one due to the sun, but as the former preponderates, in the ratio of about 7 to 3 we refer only to the former, although the latter is considered, and enters into any observation as well as into the final computation and reduction.

If then the theoretical deflection, on the supposition of an unyielding earth can be computed and the actual deflection of the vertical under lunar attraction can be observed, it necessarily follows that we have the data for determining the "give," the yielding, the rigidity of the earth,—a value of the utmost significance in geophysics.

It may be proper to state here, although it will be referred to later that observations to measure the deflection are subject to certain indirect effects among which may be mentioned the daily heating of the earth by the sun whereby a bulging of the earth's surface following the sun is caused and a consequent tilting or deflection of the pendulum. This may amount to many times—as much as 50 times the gravitational effect of the sun. Again if the pendulum is mounted say within a hundred miles or even more of the sea-coast the ocean tides exercise a dual influence. In the first place high tides loading the sea-shore bend it and the degree is dependent upon the elasticity of the rock subjected to the pressure. This effect making plausible assumptions admits of approximate estimate. Then again the mass of water brought in by high tide exerts a gravitational effect on our pendulum just as the moon does and helps to mask the true lunar effect. The bending of the earth's crust however under the superimposed water mass is for near-coast stations of far greater effect than the gravitational one of the same mass. The two latter would synchronize with each other but not with the solar heating effect. The further we advance with the problem of measuring the deflection of the vertical by lunar attraction the more complicated and difficult of realization it becomes. Low tide due to the withdrawal of water has of course the opposite effect of high tide.

From observations it has been found that the earth has about the rigidity of steel a conclusion arrived at by Kelvin years ago and by quite another line of attack and furthermore that the terms dependent upon the sun are largely influenced by meteorological conditions among which the daily heating of the earth has already been referred to. The change of declination must also be considered.

It was taken for granted that the magnitude of the deformation of the earth would show no selective azimuth but observations showed this not to be the case. Taking the mean of the observations at Potsdam, Dorpat, Freiburg and Durlach we obtain 0.47 for the meridian and 0.70 for the prime-vertical value of the theoretical value they should respectively have which means that the earth is more comprehensible in a north-south than in an east-west direction. This anomaly was puzzling. Sir George Darwin suggested that the greater rigidity of the earth in the east-west direction was due to the rotation. Prof. Love however from mathematical considerations could not assign this as a reason. He however pointed out the possibility as the difference was more marked at Potsdam which is nearer to the ocean than in Dorpat that the ocean tides might be the disturbing factor and in two ways. In the first place there must be a bending of the earth's crust under the tidal weight, and in the next place the tidal mass exercises its gravitational influence just as the moon and sun do. Acting on this suggestion the International Seismological Association at Manchester in 1911 decided to have four deformation stations established one in central Siberia, one in central South Africa, one in central North America—these three being far removed from the ocean and one in Paris where the above effects if they exist would be aggravated or increased. Canada undertook to establish the one for America and Winnipeg was first selected but it was finally decided that more satisfactory results would be obtained at Ottawa at the Dominion Observatory under constant technical supervision. Recently a concrete vault 9 by 21 feet has been built adjoining the Observatory the floor of the vault being 24 feet below the surface and the pendulums will shortly be installed.

Since the observations have been made in Europe Prof. Michelson has carried out a splendid series of observations and by quite a new method using two long (500 feet) pipes, 6 inches in diameter, the one laid in the meridian, the other in the east-west line and both underground 6 feet. They are partially filled with water and the change of level under lunar and solar attractions is measured by means of a microscope. A detailed account of the apparatus and results will be found in the March number of the *Astrophysical Journal* for the present year. We shall give his final results. He finds—

Amplitude Ratio		Phase Acceleration	
N-S	0.523	−	0.007 hour
E-W	0.710	+	0.059 hour

We see that the amplitude ratio is in pretty good accordance with the mean European results of 0.47 and 0.70, and from the position of Michelson's station—Williams Bay, Wisconsin, near the Yerkes Observatory, very far away from any oceanic tidal influences the cause of the anomaly of this difference in amplitude ratio, will very likely have to be sought elsewhere—although Schweydar (1912) agrees with Love in attributing the difference as found at the European stations to the effect of ocean tides. The phase acceleration as found by Michelson is very satisfactory being very small as one would expect. It is as he says "so small as to leave some doubt as to whether or not it is real."

We have shown in the preceding the problem to be attacked and the method of attacking it. Attention has been drawn to the very small quantities involved that is the quantities to be measured and of the numerous factors that enter into it the continuous change of the moon's position in declination and distance with the consequent change in its tide-disturbing effect. The same applies though in a less degree to the sun. To complicate our record still more we have meteorological effects impressed on the records such as the heating effect by the sun. Yet from all the tangle the physical tides of the earth show up clearly and unmistakably. At a maximum the surface of the earth rises and falls about a foot twice a day due to lunar and solar attraction. We are sitting on a long teeter (6 000 miles long with a period of a little over 12 hours) unconsciously teetering. It doesn't seem to mean much yet in it is bound up the constitution of our earth and of all objects in the universe none concerns man more than the earth. The earth is solid very solid somewhat like steel. There is no liquid molten interior as we were once led to believe.

We trust that in another year the Dominion Observatory will be able to add its share to this very interesting investigation of the deformation of the earth by the moon and sun and the determination therefrom of the rigidity of the earth, a desirable quantity in geophysics.

*In the Journal of the Royal Astronomical Society of Canada.

Comparison of the Silver and Iodine Voltameter

AN important investigation of silver and iodine voltameters was recently undertaken by G. W. Vinal, assistant physicist of the Bureau of Standards in co-operation with S. J. Bates, research associate in physical chemistry of the University of Illinois, the results of which have been published in the scientific papers of the Bureau of Standards No. 218. A brief summary follows.

Of the many electrochemical reactions which may theoretically be employed to determine the faraday, i. e. the quantity of electricity associated with a chemical equivalent in any electrochemical change, that of the deposition of silver from a solution of silver nitrate is the only one that has been extensively investigated. The values which have been accepted for the faraday from time to time have almost entirely been based upon results with the silver voltameter. This naturally resulted from the fact that the international ampere is defined in terms of the silver deposited under more or less rigorously fixed conditions and hence this instrument has been the subject of many thorough investigations both by the national standardizing laboratories and by private individuals. As a result of these investigations it has been possible for the past few years so to define the conditions to be used in connection with the silver voltameter that a reproducibility of 1 or 2 parts in 100 000 may be obtained. Until recently no other voltameter had attained anything approaching such a degree of precision.

A little over a year ago however Washburn and Bates published the results of a study of an iodine voltameter which they had devised and which was found to have a reproducibility of the same order as that of the silver voltameter. The apparently complete reversibility and purity of the electrochemical reaction in the iodine voltameter coupled with the fact that no solid deposit is obtained made it a particularly valuable reaction to employ for determining the faraday and warranted very exact electrical measurements.

We have made a careful comparison of the silver and iodine voltameters using them in series so that the deposits of silver and iodine should be strictly comparable. The best procedure learned from previous investigations has been followed in each case. Our results are as follows:

1	Ratio of silver to iodine	0.85017
2	Electrochemical equivalent of iodine	1.31502
3	Value of the faraday (I = 126.92)	96 515
4	Value of the faraday (Ag = 107.88)	96 494
5	Value recommended for general use	96 500

Nos. 2, 3 and 4 are calculated on the basis of the international ampere using 1.11800 milligramme per coulomb as the electrochemical equivalent of silver.

Removing a bit of steel from his eye.

Removing Particles of Metal from Wounds

PITTSBURGH'S great industrial plants are furnishing practically all the barbed wire used by the belligerent countries in the European war and thousands of tons of material for the making of ammunition are being shipped from Pittsburgh to Europe

This city's commercial participation in the war is greater perhaps than any other city enjoys—in so far as manufactures are concerned. But besides furnishing so much that is intended to destroy human life Pittsburgh is sending in large numbers one mechanical agent of mercy to the battlefields of France Austria and Belgium It is the powerful magnet that is taking the place of the surgeons painful and perilous probe—a machine that will prevent untold agony

The removal of pieces of shrapnel, steel jacketed bullets and other metal substances by the use of powerful electromagnets in hospitals in the European war zone has been acclaimed by many as the very latest application of science to surgery But this has been in practice in some of the Pittsburgh industrial plants for more than a year the first machine having been constructed and installed at the East Pittsburgh works of the Westinghouse Electric and Manufacturing Company As part of the relief department it has proved the most useful device ever adopted and the big magnet is here used for removing metal embedded in the flesh or in the ball of the eye.

The magnet is mounted on a box containing a resistor which is used to regulate the amount of current flow in, through the coils It requires 4 000 watts for its operation or enough power to supply one hundred 32 candle-power Mazda lamps. It is designed for operation on 70 volts As the circuit from which it draws current is used for testing purposes in the Westinghouse works and ranges from 70 to 120 volts a resistor is necessary

Not infrequently workingmen get bits of metal in their eyes or hands Before the installation of this magnet it was necessary to use a probe to remove these foreign substances a method which was uncertain and often extremely painful This magnet makes the operation very simple and painless. The part of the body in which the metal chip is embedded is placed near the pole tip of the magnet, the switch closed, and the magnet does the rest. The pole is removable, a number of different shapes being supplied for various classes of work. Bits of flying metal often penetrate the eyes of workmen When they strike with sufficient force to be embedded it is a difficult thing to extract them unless the magnet is used. The protecting coating of the eye must be cut, and there is always danger that, instead of removing the particle it may be pushed further into the eye

In the steel mills workers frequently have their hands punctured by minute pieces of flying metal which become embedded under the callous skin. When these bits are allowed to remain, in most cases the wound becomes infected. Sometimes blood poisoning results. The use of the powerful magnet insures the removal of all traces of metal from [illegible] and [illegible].

Dr G. A. Lawler, medical director at the Westinghouse plant, has compiled some valuable data on the results accomplished by the magnet. Not long ago a workman at East Pittsburgh attempted to drill one of his own teeth. The drill broke off about a half inch from the end and remained stuck in the cavity It looked as though the only way to remove the drill would be to pull the tooth. A special extension to the magnet pole was contrived and fitted to the machine. As soon as the current was switched on the drill was drawn out.

Astronomical and Mathematical Research*

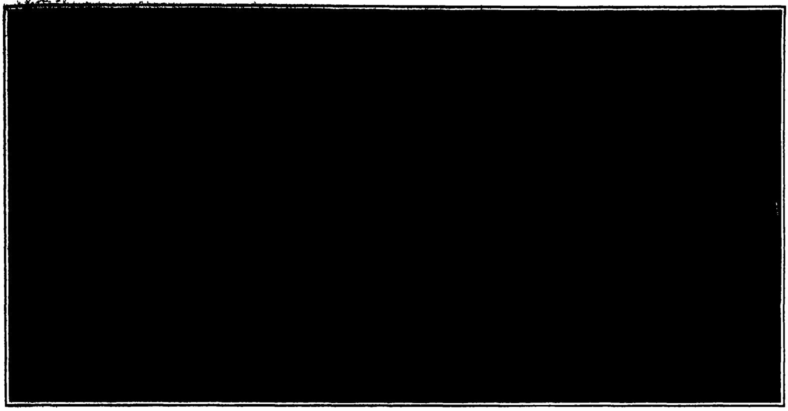
THE astronomer in common with the physicist, the chemist and others greatly needs the help that the mathematician can give On the other hand, I believe that the mathematician has something to learn from the astronomer with regard to the point of view from which he pursues his researches

This difference in viewpoint is nothing more than a recurrence of the struggle that occurs in every kind of human activity between the essentials of a subject and the technique of that subject It is a remarkable fact that the outcome of this struggle is not always in favor of the former but that mere technique is sometimes able to gain permanent mastery and to submerge completely the objects for which it was created The best illustration of this is to be found in the painter's art We know that there was a time when painting was regarded as a mode of expression through which lessons might be taught and learned, or through which at least the world might be amused But for many a long day painters have refused to take this view of their art They hold in frank contempt a picture that tells a story and their standards of what constitutes a great picture are unintelligible to any one who is not himself a painter

Astronomy and mathematics have their technique and are having their struggle with it A century ago Gauss a great mathematician and a great astronomer speaking for his times as much as for himself announced as his motto Pauca sed matura and adopted as his crest a tree laden with fruit few in number but remarkable for their perfection Such sentiments as these and the feeling that lay behind them have undoubtedly done more to hinder the progress of science than to advance it If there is any question as to what Gauss meant we have only to turn to his biography to find the answer He did not care to touch in print any subject that he felt he could not exhaust merely to contribute to it seemed to him like plucking unripe fruit Thus his published work extensive though it is represents only a part and it may be only a small part of the unremitting labor of his wonderfully fertile brain We know for example that Gauss had developed the principles of the method of least-squares while he was still in his teens but it was not until fourteen years later that he ventured into print on this subject He would doubtless have wished to delay even longer had not Legendre in the meantime unearthed and published the same principles We can make a good guess at the reasons for Gauss's delay The method of least-squares is founded upon an assumption which can be put in various forms but which always remains an assumption Gauss would doubtless have wished to prove this assumption from fundamental principles or at least to have given it a more axiomatic dress but this neither he nor any one that has come after him has succeeded in doing An even better illustration of the former attitude of men of science in the matter of their obligations to science is afforded by Gauss's part in the history of non Euclidean geometry In a letter to a friend he states that he had occupied himself extensively with Euclid's axiom concerning parallels and goes on to outline very briefly some of the results he had obtained. This letter contains all that is known of these researches A few years after it was written Lobatchewski published the little book in which he proves that the parallel axiom is no axiom at all, but a pure assumption and shows that another kind of geometry is imaginable in which the opposite assumption is made In view of this work, it would have been necessary for Gauss to revise what he had already done before publishing it He preferred however, to suppress it altogether and when after his death his scientific effects were overhauled, no trace of this subject was found among his papers

It will be understood that it is not Gauss that I am presuming to criticise, but rather the times in which he lived. That was an age when it was taken for granted that a man should think of his scientific reputation as coming first, and when the form in which he gave his researches to the world was considered as important as their content In more recent times the man of science has taken a new view of his calling and of his duties, and it is largely because of this new policy that progress has been so rapid in [illegible] directions.

*Address by [illegible] American Association for the Advancement of Science.



Entrance to the vault, showing the 3 foot thick 50 ton door open and closed with joint ground to an air tight fit

The Strongest Vault in the World

Its Massive Construction and Unusual Method of Protection

THE security vault recently installed in the new bank ing building of Messrs. J P Morgan & Co has the unique distinction of being the strongest in the world. It is 28 feet wide by 27 feet deep by 33 feet high out side and is divided into three stories The walls are 2½ feet thick made up of a harveyized nickel steel armor plate lining surrounded with rock concrete rein forced with double and treble sections of 125-pound nickel steel rails, interlocked at all corners and bound with multiple angle frames and tie rods The outside is finished with a steel panelled cladding

The main entrance is guarded by a round door which is made without stepping or rebates, and is ground into the frame for its entire thickness of 36 inches. This door is of composite construction the inner half being of nickel steel armor and the outer of cast steel with concrete, jail rods and anti-oxyacetylene cutter burner proof sections between This door with its boltwork and hinges weighs 50 tons and is so well balanced that it can be swung with one hand.

An emergency door of corresponding thickness and construction but of lesser size obviates the possibility of lockout and furnishes means for ventilation the air being changed every two and one half minutes

The three floors of the interior are equipped with security closets and safes, filing fixtures trucks etc The floors are finished with cork tile Stairways afford communication between floors and an elevator is pro vided for trucks and packages A level entrance is afforded by lowering platforms

The vault is provided with two systems of electric lighting a high tension which is regularly used and a low tension which is brought automatically into service if the high tension fails.

A complete system of calls alarms and telephones is also installed, in addition to a telephone permanently connected to Central for use if a person is locked in the vault The night lights also run continuously

Time locks are applied directly to each door which is solid and has no spindle holes the combination locks and bolt throwing mechanism being applied to the jamb

All of the combination and time locks and bolt throw ing mechanism upon the inside of the vault are covered with heavy steel plates which obviates an almost uni versally weak condition where the putting of a small hole through the vault walls provides direct access to the locking connections

A protected and electrically lighted dial with revolv ing pointers has been substituted for the standard com bination lock dials this affording greater convenience, and insuring the operation of the combination against observation from anyone except the operator

Electric protection is applied over the entire vault and is connected with Central Office service The vault is arranged for observation by means of patrol passages and mirrors around the four sides underneath the bot tom and across the top

The work is fire proof water proof burglar proof and mob-proof and as a whole represents the very last word in high class vault construction

Refractory Materials and the War*

THE successful manner in which the Germans have developed the manufacture of various heat resisting materials has been clearly demonstrated since the ad vent of the war and as time goes on the absence of sup plies becomes more and more trying in those industries where heat-resisting materials are required The manu facture of chemical porcelain for instance, is almost unknown in Great Britain, and we have to depend for supplies of this ware on goods which are obtained more or less surreptitiously through neutral countries such as Holland and Scandinavia. The supplies stocked by dealers have never been very large, and these were rapidly depleted. This encouraged a number of British potters to make some simple attempts at the manufac ture of refractory porcelain, but most of them soon abandoned it, for though they could make ware which would withstand acid they could not produce a porcelain with the insensitiveness to sudden changes in tempera ture which is so characteristic of the Saxon ware. Other experiments are being continued, and it is hoped that before long this ware, which is so important to chem ists, will be successfully manufactured in this country at prices not markedly higher than have been paid for the imported material. Meanwhile, the use of fused silica ware or "vitreosil" is increasing, as it will meet all the requirements, but is more costly than porcelain.

The importation of bricks for building coke ovens and other furnaces from Belgium and other parts of the Continent has necessarily ceased during the war Fire bricks of equal refractoriness can be purchased in this country but they do not satisfy the tests which the Continental builders of coke ovens consider to be essen tial British firebrick manufacturers are making ex tensive efforts to overcome these objections and are gradually increasing their ability to make firebricks to fit any reasonable specification They have much to learn however though they have made much more rapid progress since the war began. Firebricks for furnaces and similar purposes where the specifications are less stringent can be made successfully in this coun try though the prices of firebricks in extra European countries before the war were largely in favor of those made in Germany This was due to the much larger works organised on an entirely different basis and working on a system of "dumping" which does not appeal to British manufacturers It is a curious fact that with inferior materials to those commonly used in Great Britain, the Germans have turned out better fire bricks and have been able to guarantee results to an extent which British firms have found impracticable. With competition less severe in some respects British manufacturers are now turning their attention to im proving the qualities of their goods, as in the past they have concentrated their minds on the production of cheap bricks. With adequate technical assistance of a kind not generally available they will be able to make great improvements in quality and should in time be able to produce better bricks than any now on the mar ket. Retorts for the manufacture of coal gas cannot now be imported from Germany so that gas engineers are compelled to use the home-made products There is much divergence of opinion as to the relative values of British and German retorts and it has not been un usual to find German engineers importing British re torts while some British engineers have preferred to purchase German ones Here again British manufac turers are trying to meet the demands as far as they are able to do so.

The chief difference between British and German re fractory materials may be traced to the difference in the ownership and management of the firms In this country refractory materials are chiefly made by men who have worked themselves up from a small begin ning—or the descendants of such men—their chief char acteristics being that of a workman whose knowledge and experience have been gained almost entirely in the workshop, and whose theoretical knowledge—either of chemistry physics or mechanics—is almost negligible The German manufacturers of refractory materials on the contrary have almost invariably had a sound train ing in chemistry and engineering they approach the manufacture from an entirely different point of view namely that of the user turned manufacturer Conse quently they are more impressed with the needs of the user while the British manufacturer is chiefly im pressed with the difficulties of manufacture and the limitations imposed by his material If once this bias could be overcome—and the only remedy is the better education of the manufacturers—there is no question that better refractory goods can be made in Great Britain than can be obtained from the Continent for the same price.

The Educational Scrap Heap and the Blind Alley Job

A Vitally Important Economic and Social Problem

By L. W. Dooley

If there is one word in the English language which thoroughly designates the spirit of the modern age it is the word *efficiency*. In manufacturing, in merchandising, in philanthropy, in church, on the farm, everywhere we are convinced that preventable waste is a thing to be discovered, to be corrected. To many men the idea of efficiency is rather indefinite, meaning something above the average, but not capable of any precise definition. As a matter of fact, efficiency is very definite. It is the percentage of useful work or effect which is obtained by man or machine in comparison with what may be termed the maximum effect attainable. Manufacturers are not satisfied with the mere entering of raw material into the factory, and the finished product leaving by another door. They desire to know the amount of waste, and are very uneasy if too much raw material is wasted or placed in the scrap heap. Waste is repugnant to us to-day. This same cry of greater efficiency of the modern time has entered our educational system. Citizens and public spirited men are criticising our schools through the newspapers and magazines. They claim that there is great waste in our schools, the essential is neglected, and the boys and girls are not properly prepared for life. The practical abandonment of the apprenticeship in the country, except in a few isolated places like Brown & Sharpe Manufacturing Company, is bringing about a want of skilled workmen which the modern industrial system is failing to supply. On the other hand the great number of unskilled workers has increased, and all of them have not been able to obtain employment. The great industrial demand of the present, and of the recent past is making this want felt more and more sharply. The whole country is awakening to the necessities of the case, and demanding a remedy. Organized educational forces are moving rapidly in the direction of making our school system more practical.

With the idea of increasing the efficiency of our school system in this direction, a commission was appointed some six or seven years ago to investigate the need of practical education throughout the State of Massachusetts. The commission naturally first studied the need of industrial education in the great manufacturing centers. In the course of their investigations of the condition of the employment of children between 14 and 16 years of age, they found that nearly five sixths of the children in the mills have not graduated from the grammar schools, and a very large proportion have not completed the seventh grade, while practically none had a high school training. To be more specific a conservative estimate would be that every year in the State of Massachusetts from 20,000 to 30,000 boys and girls, on reaching the age of 14, leave the schools to go to work. This army is four times as large as the group which, at approximately the same age, enters the high school. Only one of every six of these children taking up some wage earning occupation has reached the eighth year or grade of the elementary schools, only one of every four has attained the seventh year, only one out of every two the sixth year. The record of the number of pupils that enter the high school and colleges in Massachusetts is as good proportionally as any State in the Union. So that above figures would be a conservative figure for the rest of the country.

In most States the law compels children to remain in school till they are fourteen years of age, and under ordinary conditions they should have completed the grammar school at the age of fourteen or thereabout. The question that comes to one's mind is, Why has not this child completed the grammar school before going to work?

The public school system is divided into divisions called grades, based upon the chronologic age of the individual. Pupils are graded in a school in order to keep as far as possible the mental and physical development equilibrium. A great many children of the same chronologic age may be safely placed in the same grade in the school, but since individual children differ from each other in mental and physical development to a marked degree, a wholesale classification has proved in many cases to be inadequate.

The different types of children may be illustrated by a straight line, one end of which might be called motor minded and the other abstract minded. The motor minded or hand mind child is one with a craving for achievement, to do and not to study. He has a natural dislike for books, and finds it possible to understand abstract principles only by having an actual experience with them. The abstract or book minded child is one who has no difficulty in committing to memory abstract principles and likes to study books. Between these two limits are shades of different types. The average child is motor rather than abstract minded.

The test for promotion in our present school system is a literary one. The abstract minded child with his quick memory has no difficulty in passing the promotional tests, while the motor minded child, without quick memory, fails of promotion and becomes what the teachers call a retarded pupil. A child repeating a grade feels that he is a social outcast among the pupils and loses interest in school. Then again, a child of twelve cannot be expected to be interested in the methods of teaching and content of information adapted for a child of ten.

There can be but little question that our school system has lagged behind the development of those forces of business organization with which they should be clearly articulated. Our school system is only just now entering upon the stage of efficiency which industry has long since considered. Nowadays educational experts are beginning to see that the dull pupils can be rescued and that stupidity has various causes, a great many of which may be cured. In years gone by, if a girl or boy did not get on well in school, he or she was most likely noted as being just plain stupid, and called a dunce, and allowed to drag along until the day came, when he or she would leave school. These children have been referred to as the scrap heap of the public school system.

Very wide and careful investigations have established the fact that a great many parents feel that when their children reach the age of fourteen they should go to work. The children in a few cases are not obliged to leave school because his parents are very financially able to keep him in school, but because they (the parents) went to work when they reached the age of fourteen, and they do not see how a further training in the public schools would aid their son or daughter in direct training for earning capacity. On the other hand the vast army go to work for economic reasons. This educational scrap heap, designated by our present school system as worthless, has great imitative power and capacity for mechanical work and experiences no difficulty in obtaining work at a high initial wage in what are called by our social workers "blind alley" or "dead end" employment, that is, employment such as messenger boys, attendants in bowling alleys, doffers in mills, attendants in glass factories, etc., in which the experience gained under the present industrial and educational conditions are said to form no basis for advancement into more skilled and better paid work as the child grows older. When these young men reach the age of eighteen they have passed their usefulness in this type of juvenile work, and find there are not positions enough for them in other parts of the mill, and they leave and form our great unskilled army, and fill our public employment offices. There are plenty of positions in the metal trade, etc., demanding mechanical experience that these young men might fill with profit if they had received a training on some kind of a part time basis while they were engaged in highly specialized juvenile occupation.

The problem to-day is how to retain our industrial supremacy, our present industrial organization of highly specialized work, and to develop the whole boy and girl so that we may have successful men and women with industrial habits to live useful and happy lives.

This cannot be done by groups of social workers in this country attempting to tear down our industrial system by forcing unjust legislation on the community such as compulsory full time education for children up to sixteen years of age or over. Our social and industrial system is a growth, and we are at the present time passing through the transition period of a change in our industrial and social system, the like of which has never been experienced in any equal space of time during the world's history. All this means readjustments of our social institutions, particularly the educational system. The school and factory must work hand in hand. The school must supplement the factory in such a way as to overcome the deadening effect of highly specialized work, and at the same time give a training that will develop the child so that when he has passed his usefulness in that juvenile work he may have the training and intelligence to enter other lines of work.

Any attempt to degrade our factory system, which employs practically two thirds of the children that have left school as soon as the law allows, by saying "it is ignorance on the part of the parents who allow the child to enter the mill or factory, and that neither power nor advantage is gained by entering the industry at an early age, and the child who does enter associates himself with our most undesirable population" is detrimental to the child and organized industry.

What a terrible indictment to place on our factory system. Let us examine it and see whether it is true or not. There are certain branches of industry, such as textile and glass, etc., requiring low or medium grade skill that are absolutely dependent for their operation on a supply of labor of boys and girls between the ages of fourteen and seventeen. A conservative estimate based upon reliable information shows that practically two thirds of the children that go to work after leaving school go to work from the immediate grammar grades in the above-named industries.

The textile industry employs more children at the age of fourteen or under than any other industry, and consequently is held up to the public as the most flagrant violator of child labor laws. It may be of interest to study the kind of juvenile work performed in the textile (employment) industries. Both boys and girls of fourteen or under can readily find employment in mills performing simple and easy operations such as doffing (replacing full spools on spinning frame with empty ones), piecing (placing broken ends of yarn together), supplying various adult machine operatives with bobbins of yarn, etc. These operations can only be performed to great advantage by children under seventeen. What they do receive in the line of learning is the development of useful industrial habits that are very valuable during the period of adolescence as they remain with the child.

In all these industries the work is intermittent, that is, it is of a character that allows for periods of rest and requires the attention of the operators for not more than two thirds, or half, the time; therefore, it does not require the consecutive labor demanding concentration, and the attention of the children and the care of the machine. Children at this age, between fourteen and seventeen, have not the endurance, that is, the bones have not developed sufficiently to allow consecutive work. To illustrate: the average boy or girl of sixteen or seventeen will actually give in work at least a half hour a day more than the average child of fourteen or younger. The child of the same age, sixteen or seventeen, will do at least 5 per cent more work, hour for hour, with a correspondingly less amount of waste material and damage to finished product. The work will also require less supervision, and will be of higher grade when finished.

That is the reason why the other so-called skilled trades, such as the higher branches of the metal and machine trades, the building trades, and printing trades, etc., do not care to receive boys or girls until they are seventeen. Girls find opportunities in skilled trades as typewriting, stenography, millinery, dressmaking, machine operators, and are not wanted until they are sixteen or seventeen. The above trades of high grade allow for individual action, the pupils have an opportunity to study their work and make comparisons between their past experience and their daily work. It also allows for the initiative and independence of the pupils and leads to a progressive development from a simple process to one requiring a higher degree of skill and intelligence.

Why cannot the factory system provide this training in the same way as some of the higher branches of the metal trades? Competition will not allow it. Greater changes have taken place in the organization of industries in the United States during the last generation since the factory system was introduced than during any other period in the world's history.

No industry shows this development better than the textile industry. During the past fifty-four years there have been practically no inventions involving new principles of textile machinery, but there has been marvelous improvement in the efficiency of the machinery.

In order to reduce our so-called educational scrap-heap it is necessary to change our school system so that it will educate the whole boy and girl of this day. A manual training department should be attached to every school in this country. Children should be taught as soon as they go to school to use their hands, as the father and mother did in the small communities a generation ago. It is very important that they should

be taught when they are young. The aim of all this will be to make every boy and girl, when they reach the age of fourteen, know how to use their hands with some degree of skill, to be "handy" in addition to the ordinary academic work. For the majority this will not necessitate any more hours of work (school). We have evidence that by reducing the time allotted to academic work and substituting manual work the mind will be stimulated. In addition, the child will not leave the school with a feeling of repulsion.

In order to look after the welfare of the individual child it is necessary to know definitely the time he should begin to work and the kind of work he is able to do. Physicians tell us that the mental and physical condition should not be overshadowed by being brought into use before the development adapted to such use is established; and on the other hand, that functions, both mental and physical, are weakened by not being brought into use when they are ready to be used.

This means that the mental condition of the child should be carefully determined to see whether the child should be allowed to work at all. Before this is done it is absolutely necessary to know the kind of work the boy or girl is to perform. After it is determined by tests that he has the mental equipment and the degree of knowledge necessary to do juvenile work, the next problem to be solved is whether his physical condition is such that this particular kind of work will not harm him. Since labor differs in character, occupations should be classified and the boy or girl should only be allowed to perform the character of work that is best adapted to his physical condition.

It is evident then, that some additional aid for determining the fitness of an individual, either for his school or physical work, beyond the usual superficial examinations now conducted for fitness, should be required. A very eminent physician of children's diseases, Dr. Thomas M. Rotch, has for some years been making a study of additional means of determining the relation of physical fitness to certain degrees of labor and to school work.

The close relation which is known to exist between physical growth and the development of the epiphyses led him to make some investigation by means of Roentgen ray on the living anatomy of early life during the different stages of development. A study of a large number of cases showed that under normal conditions all the centers of ossification progressed with comparative regularity, and that the degree of development of the wrists and hands represented to a fair degree that of the entire body framework. This correspondence of the development of the wrists and hands to that of the rest of the skeleton is especially fortunate, as it is evident that the wrists and hands are the most available parts for routine examination in a large number of cases. This anatomic relation has been substantiated by other physicians of high standing.

So that a more reliable and very practical method of conducting a physical examination may be substituted in which results will show whether the child has the proper physical development to perform physical work of a certain character. This method of physical examination is at present conducted by the United States Government at their naval academies.

The children who go to work in the mills leave school at a very tender age, a time when they have little liking for school or interest in the subjects they learn there. They have received absolutely no industrial training for the work they are going to do. The industrial operations of mills and shops of to-day are so highly specialized that the operators are not obliged to exercise any of the training they have received in school. The result is that they rapidly lose the habits of thinking and the power of initiative, and when they reach the age of eighteen, and cannot any longer perform the operations of doffing, etc., on account of the stiffness of fingers they become dissatisfied and leave the mill and form the army of the unskilled.

Before the advent of the factory system juvenile apprenticeship was common on the farm, the household, and in the trades. The child was taught the practice and theory of his trade. In addition to learning the orderly processes of his trade and seeing the necessity of continuous effort, he learned the practice of the small economies which are the basis of frugality and thrift. He learned to fit means to ends and become ingenious and inventive. He learned that when many worked together every little helped, and that only by mutual help could the best results be obtained.

We must act on the principle admitted by everybody who knows or cares anything about education, that the way to secure a good training for the mind is not to end the school life at the most plastic period, fourteen years of age, or in the case of foreigners, as soon as they can pass an examination, but to insist that every boy shall spend a certain number of hours a week under educational training and sound teaching till he reaches manhood.

Experience has shown that evening schools do not appeal to tired children. Boys between fourteen and seventeen have the "gang spirit" in them, and after working hard all day they desire companionship of their fellow workers on the street corners, or moving picture shows. Their eyes, wearied with long labor in the day, cannot endure the fatigue of book work by night, but they are revived and changed by the splendor of gay lights of the theaters and moving pictures. Physicians confirm this experience by stating that while these children require education, they should not attend evening schools after working nine or ten hours.

It may be said, therefore, that while we have built up in the industrial centers of the United States at an enormous expense a colossal system of education offering opportunity for a general education and prepare for admission to colleges and higher technical schools, we have failed to provide for the greater majority of boys and girls who enter industrial life in juvenile occupations. That is, a practical relation between industry and education for that great mass of pupils who are going to work with their hands as soon as the law allows. We allow the results of our educational system as far as these children are concerned, to be very largely wasted and lost. We cease to educate these all important years, during which we all know that education is most needed and valuable to our working people.

The German government has solved the educational problems in a more satisfactory manner than any other country. According to their scheme of education, every worker in a profession, trade, or commercial pursuit, must not only have a general education, but technical preparation for the particular work selected by him. In the United States we believe in the same policy, but apply it to those entering the profession only, disregarding the great mass—95 per cent—that leave school at fourteen.

Germany, by recent legislation, insists that every child be under educational influence till the age of eighteen. The child may leave the common school at fourteen. He may go to work, to a higher school and prepare for college or to a technical school. If he goes to work, he must attend classes called continuation schools, classes to the extent of eight or nine hours a week. In the United States he may leave school at fourteen, and is not obliged to attend any other school.

In order to overcome the educational weakness of our present dead end or blind alley occupations, we must provide for working youths opportunities on a part time system, an education which will meet with their interests and tastes, assisting each to become proficient in some line of work that he may enter after passing his usefulness in the so-called blind alley position.

Experience of educators in this country and abroad who have worked in large factory centers agree that it is a positive harm to retain the great mass of children between the ages of fourteen to eighteen in a school on a full time basis in spite of the many assertions from social leaders to the contrary. They have neither the mental equipment nor the interest to devote so much time to academic work. They have descended from ancestors that mature early in life and have intensely practical ideas.

Therefore, they should receive an education adapted to their physical and mental equipment—part time system of education. The educational training on a part time basis for boys in the so-called skilled occupations, where there are sufficient opportunities for them to remain all their life should be *for greater efficiency and* civic betterment. For the boy in the so-called unskilled or factory operations, where there is a lack for further advancement there should be a trade training so that he may receive during the years from fourteen to eighteen the beginning of a skilled trade, so he may be accepted into one of the skilled trades as a useful beginner. In this way the part time school acts as a port of entry from unskilled to skilled trade, and removes the strong feeling that exists to-day that our present school is undemocratic in that it takes care of 10 per cent in the community and ignores the 90 per cent who must work largely with their hands. It will meet the great educational needs of our splendid industrial system by supplementing the highly specialized experience with an antidote of more general practice and theory.

For girls in skilled vocations, the training must be for greater efficiency—a supplementary trade training in case of seasonable employments and a training in housekeeping. Since women have more or less to do with the home, it is doubtful if there is a more effective system of education than housekeeping. It will bring both health and happiness to the home.

The efficient democratic school of the future must have a course of study in the elementary schools that will be adapted to the aptitudes of the great mass of children who are motor minded and must be reached through the manual and objective methods of teaching. In this way pupils will be attracted to the schools and not leave as soon as the law allows. Vocational advisors should be established to assist and direct children in selecting vocations and while attending compulsory part time education. Intelligent selection of an occupation is the result of intelligent preparation. We cannot expect young people to find themselves vocationally without furnishing them with any raw material for thoughtful selection. Our public school system should audit our social accounts and publish the opportunities available to young people, that they may choose their life work scientifically, and in this way reduce our scrap-heap of unskilled labor to a minimum. Blind alley jobs will then become ports of entry into more skilled and profitable positions.

Trinitrotoluene in the War

IN a recent article reference was made to the high explosives used as bursting charges for shells, the most important being the much-discussed trinitrotoluene, used largely by the Germans. The following summary, from *Nature*, of an able contribution on the subject, published in the *St. Thomas's Hospital Gazette* for December, will prove a useful supplement to the previous article.

Few people realize the exacting conditions which a high explosive for shells must fulfill; these may be summarized as high bursting power, stability in storage, insensitiveness to shock on firing from the gun and on impact of the projectile, where it is desired that penetration shall precede bursting. Yet it must be possible to cause the material which withstands such drastic treatment to detonate when required with frightful violence. It is a case of reconciling the irreconcilable. Further points are safety in handling in the shell factory and the suitability for producing maximum density of loading, say by some such method as melting and pouring into the shell.

The brisance, or bursting power, is shown to depend on the potential energy of the explosive, the velocity of detonation, and the degree of concentration (density of loading)

It will be realized that few substances will fulfill such conditions, and the number will be still further reduced by difficulties and cost of manufacture. The paper discusses the four most important explosives which have been tried for this purpose, namely picric acid (lyddite), trinitrotoluene (TNT), tetranitromethylaniline (tetryl), and tetranitraniline.

The trinitrotoluene is the symmetrical isomer (1 : 2 : 4 : 6) melting at 80.6. It is manufactured by dissolving *ortho*nitrotoluene in concentrated sulphuric acid, nitrating first to the dinitro and finally to the trinitro stage, the purification being effected by recrystallization from ethyl alcohol containing a little benzine.

Data are given of comparative trials of TNT and picric acid, both in France and Germany. In velocity of detonation and with the lead block test (increase in size of cavity on firing a charge) the advantage is with lyddite, as the following figures demonstrate:

	Lyddite.	TNT.
Velocity of detonation	7,745	7,140 meters per second.
Lead block test	228	218 cubic centimeter.

TNT caused, however, a greater displacement of earth than lyddite when fired in a bore-hole 1 meter deep.

Except in the last instance, picric acid held a decided advantage throughout, and the question at once arises: Why, then, has trinitrotoluene been adopted by Germany, Russia, Italy, and other countries in preference to the picric acid that is still mainly used by us under the name of lyddite, and by France under the name of melinite? The struggle between the two explosives has been long and of doubtful issue, but it has now probably ended in the victory of trinitrotoluol.

In furnishing the answer to this conundrum the writer continues:

We have seen it to be inferior in regard to power, velocity of detonation, and density of concentration; its advantages lie in its greater insensitiveness to shock, its freedom from poisonous dust and fumes, the much lower temperature at which it can be poured into shells, and its chemical indifference to substances like lead and iron which are liable to form dangerous picrates. When firing a shell against a ship's armor, at certain limits of the thickness and toughness of the armor-plate and of the velocity of the shell's impact, picric acid would explode when trinitrotoluol would perform its work efficiently, and the latter is therefore better adapted to a high-velocity shell of large caliber.

Since TNT contains too small a percentage of oxygen for complete combustion, attempts to use it incorporated with bodies rich in oxygen, such as potassium chlorate, have been tried. The Belgian high explosive, "macarite," is stated to consist of 30 parts of TNT and 70 parts of lead nitrate. A very high density of loading is thus attained, but the velocity of detonation of macarite is given as only some 4,600 meters a second.

In concluding his article, the author says that tetranitraniline or tetryl seem to be the only known substances that may supersede trinitrotoluol.

Gyrostatic Action*

As Applied to Torpedoes, Submarine Craft and Aeroplanes

By Jas. G. Gray, D.Sc., F.R.S.E.

It is the object of the present paper to describe a number of gyrostatic devices available for controlling moving bodies. The gyrostatic motor cars and bicycles which are described in this and my previous paper to the Institution should be regarded merely as a kind of by-product; the real object of my work on gyrostatics has been directed to the production of gyrostatic controls for torpedoes, submarine craft, airships and aeroplanes. The motor cars and bicycles do, however, prove conclusively that the principles and methods of operation that have been evolved are dynamically correct, and that the application of these principles to problems of submarine and aerial warfare promises to result in the production of machinery of great value.

In all the cases considered in the present paper the stability of the gyrostatic system is derived directly or indirectly from the propelling system. Hence these cases do not include solutions of the monorail problem, for they have not true stability when they are at rest or moving in the backward direction. The tandem wheeled motor cars to be described, for example, although they may be set to run in a perfectly straight path, will not balance on a single rail. The devices, however, have properties which are not possessed by any of the monorail devices so far evolved, and it is these very properties which promise to be of value.

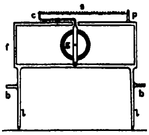

Fig. 1.—Stilt top

In Fig. 1 is shown a form of stilt top. A gyrostat is mounted as shown in a frame f. The gyrostat is on cross bearings carried by f. When f is upright these bearings are in a vertical line. The crank c, which is rigidly fixed to the frame of the gyrostat, is attached to one end of a stretched spring S, the other end of which is fastened to a point p in the main frame. If the fly wheel of the gyrostat is set spinning and the top placed on a table with the plane of the fly wheel and the main frame f in the same vertical plane, and left to itself, it will balance for a considerable time if the spin is great. Initially f is in the same plane as the spring S. The stretching force in the latter, therefore, exerts no moment on the gyrostat about the cross bearings which attach it to f; but as soon as the gyrostat precesses on the latter bearings the crank gets out of line with the frame and the spring exerts a moment in the direction of the precessional motion.

The entire top when vertical is unstable without rotation of the gyrostat fly wheel, about the line of contact of the feet with the table. Further, in consequence of the stretched spring the gyrostat is unstably mounted on the frame. Thus the gyrostat is doubly unstable without rotation of its fly wheel.

The action of the top is as follows: Starting with f in a vertical plane containing the crank and spring, suppose it to tilt over on the table. As a consequence the gyrostat precesses about the cross bearings, and the precession is aided by the spring, with the result that the frame erects itself into the vertical. But at the instant at which the frame has attained the vertical the spring is out of line with the frame, and is exerting a moment on the gyrostat. Under the influence of this couple the gyrostat continues to precess about the line of contact of the feet with the table; that is, the main frame passes beyond the vertical position, after which the lateral instability of the entire structure results in the establishment of a couple tending to accelerate this precessional motion. This couple causes precession about the cross bearings bringing the crank and spring into line with f; but when this alignment occurs the entire top is inclined from the vertical, and so on. The amplitudes of these oscillations continually increase, and finally the top falls over.

Again suppose that, starting as before with f, and the crank in one vertical plane, the crank gets out of line with f. As a result the spring exerts a moment on the gyrostat which, in consequence, precesses about the

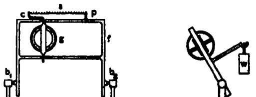

Fig. 2.—Stilt-top set up on fork and pedestal mounting

line of contact of the feet of the top with the table. This precessional motion is automatically accelerated, and the spring is thrown into line with f, which is now inclined from the vertical, and so on.

It will thus be seen that starting with the main frame and the spring contained in one vertical plane the top balances; and if the spin is great the balancing power is very considerable. But there is not true stability; oscillations are set up. The frame oscillates to and fro on the legs; the gyrostat oscillates to and fro on the bearings which attach it to the frame. If the stability were real the top, if started in an inclined position, would erect itself into the vertical one with the spring in the plane of f.

It is interesting to consider the action of this top from the energy point of view. The entire structure is unstable on the legs, and thus possesses a stock of potential energy. Again, potential energy is stored in the spring. Obviously the entire stock of potential energy is a maximum when the top is upright with the crank in the plane of f. When the frame tilts on the legs, and the gyrostat turns on the frame bearings, energy is dissipated in friction. Consequently, once the frame has become inclined to the vertical, or the crank has got out of line with the frame, the system cannot return of itself to the position of maximum potential energy, that is, to the position in which the crank and frame are in one vertical plane. To obtain complete stability it is necessary that the energy dissipated in friction should be made good.

Returning now to Fig. 1, it will be seen that the stilt top is provided with two projecting pieces b b. So designed it may be set up in a fork and pedestal mounting, as shown in Fig. 2. The fly-wheel of the gyrostat is set into rapid rotation, and the arrangement mounted on the fork with the frame f and the crank in one vertical plane. The fork is grasped in the hand of the experimenter. Now, suppose the arrangement to tilt on the fork bearings b_1 b_2. The gyrostat precesses on the bearings that carry it on the frame, and immediately a couple, due to the spring, tending to accelerate the precessional motion, comes into existence. At the same time the experimenter turns the fork, so as to bring the frame into line with the crank. Providing this operation is properly carried out the frame is restored to the upright position and the crank is in line with it. The spring has supplied energy to the frame in restoring it to the upright position, and the potential energy lost by the spring has been made good by the experimenter. Thus the experimenter, by causing the frame to follow up any precessional motion of the gyrostat endows the system with complete stability.

Now, let a weight W be attached to one side of the frame. This at once causes precession of the gyrostat and the establishment of a couple due to the spring.

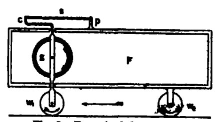

Fig. 3.—Two-wheeled motor-car.

The experimenter turns the fork so as to bring the frame into line with the crank. Here energy is being transmitted from the spring to the frame by means of the gyrostat, and at the same time energy is being supplied to the spring by the experimenter. The frame turns on the fork bearings, so as to raise the weight against gravity. The precessional motion continues until the center of gravity of the entire arrangement is vertically above the line of b_1 b_2. The spring is now in line with the frame, and consequently its stock of potential energy is precisely that which it possessed at the start of the experiment. The energy required to raise the weight against gravity has been supplied by the experimenter.

Fig. 3 illustrates the application of the principles just described to the construction of two-wheeled and four-wheeled gyrostatic motor cars. The figure shows a car in which the wheels, of which there are two, run in tandem. The gyrostat g is mounted on top and bottom bearings provided in the main frame F. One of the axles which carry the gyrostat is extended, and terminates in a bearing for one of the wheels W_1 of the car. The construction is such that this wheel is in the plane of the fly-wheel of the gyrostat. The back wheel is geared up to driving mechanism. The gyrostat is fitted with a crank and spring device, as already described. Arrows on the wheels indicate the direction of motion of the car.

Let the fly-wheel be set into rapid rotation, and the car placed on the floor with the main frame, the fly-wheel of the gyrostat, the two wheels supporting the device, and the crank in one vertical plane. It will be clear from what has been said that, if left to itself, the car will balance on the wheels, but with the accompaniment of gyrostatic oscillations of continually increasing amplitude. If it were allowed to remain stationary the device would eventually fall over. But when driven in the forward direction it is completely stable. The gyrostat steers the car, and when precessional motion on the cross bearings takes place this results in the main frame F, to which the end of the spring remote from the crank is attached, being brought into line with the crank. Thus the action is precisely that described above for the stilt top when mounted on the fork bearings; but the action is now automatically perfect. The stability is complete when the car is moving in the forward direction. [illegible] tend [illegible] the centre of gravity directly above the line of [illegible]

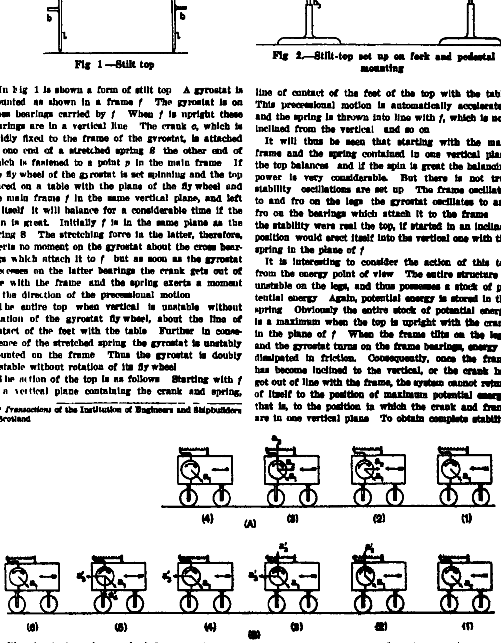

Fig. 4.—Action of two-wheeled gyrostatic motor-car. (A) March of vectors following on tilting of car toward reader, (B) March of vectors following on displacement of spring from central position.

* Transactions of the Institution of Engineers and Shipbuilders in Scotland.

the wheels with the ground, and thereafter proceeds in a straight line path.

In this device the gyrostat derives the stabilising forces from the spring, and when the stock of potential energy possessed by the spring is drawn upon, an equal amount of energy is automatically supplied to it by the propelling system The gyrostat thus detects any tendency to tilt in either direction, calls upon the spring to supply the necessary correcting forces, and upon the

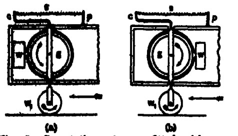

Fig. 5.—Gyrostatic motor-car fitted with controlling weights.

propeller to maintain constant the energy possessed by the spring.

The gyrostatic action of this device is illustrated graphically in Fig 4. Suppose the car to start perfectly balanced and upright. This condition is shown in (1) of the diagram (A) of the figure. The arrow at the back of the car shows the direction of motion, and the curved arrow attached to the gyrostat indicates the direction of rotation of the fly wheel The angular momentum may be completely represented by a straight line drawn out from the fly wheel toward the reader Thus a_1 is the spin axis. Now the car is unstable about the line of contact of the wheels with the ground, and hence, after a short interval, a tendency to tilt in one or other direction will assert itself Suppose that when the car is in the position (2) there exists a tendency of the device to tilt towards the reader This tilting couple is completely represented, according to the usual convention, by a line a_2 (the couple axis) of proper length drawn as shown in (2) toward the back of the car The gyrostat precesses so that a_1 turns toward the instantaneous position of a_2, the crank comes out toward the observer, and a couple tending to turn the gyrostat counter-clockwise, as viewed from above, is established. This couple is represented by a_3 in (3) The gyrostat now precesses so that a_1 moves toward the instantaneous position of a_3, that is, the car erects itself against gravity, it moves away from the reader about the line of contact of the wheels with the ground. The tilting couple is thus reduced and finally annulled. Further, and this is a point of the greatest importance, in consequence of the fact that the gyrostat is steering the car, which is moving in the forward direction, the want of alignment of the crank and car is being reduced. Thus a_2 and a_3 diminish together, and the car is finally left as in (4) of the top diagram of the figure

Now to investigate the annulment of the instability introduced by the crank and spring This will be understood from the lower diagram (B) of the figure In (1) the car is shown balanced in the upright position with the crank in line with F Suppose it to get out of line with the car without there being any tendency of the latter to tilt (this may be due to a jolt) Let the displacement of the crank be towards the reader The couple brought into existence by the want of alignment is represented by a_2 of (2), and the gyrostat turns so that a_1 moves toward the instantaneous position of a_2, the car turns over from the upright position (away from the reader) and a couple represented by a_3 of (3) comes into play The gyrostat now turns on the vertical bearings in the direction which results in a_1 moving toward the instantaneous position of a'_3—that is, in the direction which brings the crank into line with the car The couple due to want of alignment of the crank and frame disappears, but the car is left inclined to the vertical This stage is shown in (4) The gyrostat is precessing on the vertical bearings, and a couple represented by a'_4 (5) is introduced. The resulting precessional motion and the forward motion result in a'_3 and a'_4 going out of existence, as already explained, and the device is left as shown in (6). It is now upright, with the crank and frame F in line.

A little consideration will show that the faster the car travel the more perfect is the action. As a matter of fact, the cars constructed by the author are perfectly stable even when moving very slowly The action is, as already explained, quite automatic. Once the upright position is attained it is never departed from, and the car moves in a perfectly straight path. The effect of [illegible] to the car tending to upset it is to [illegible] which are quickly wiped out.

[illegible] the effect of attaching a [illegible] F is to cause the car to bank up [illegible] path. The properties of the device are, however greatly added to by attaching a weight W to the frame of the gyrostat, as shown in Fig. 5 (a) and (b) If the gyrostat is spinning in the direction in which the wheels of the car rotate, the weight should be placed as in (a) If the direction is reversed the weight should be as in (b) Consider

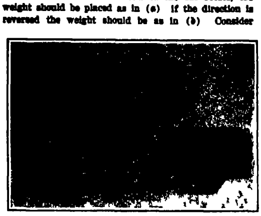

Fig 6.

diagram (a) Let a side weight be supposed attached. The car banks up against this weight, with the result that the line of the frame bearings becomes inclined to the vertical A couple acting against the spring is then applied by W A steady state is soon arrived at in which the couples applied to the gyrostat by the spring and by W are equal The car is not sufficiently banked up to account entirely for the side weight and the gyrostat precesses continually The car moves in a circular path

When the side weight is removed the device straightens itself out and proceeds in a straight path Attaching the side weight to the other side of the car causes the latter to move in a circular path in the opposite direction to the former one

Fig 6 is a photograph of an actual working model of a two-wheeled car constructed on the above principles In this model the front wheel is the driven one The gyrostat is carried on the main frame on vertical bearings It steers the back wheel through a link attachment The car is available for demonstrating the principles which have been explained A much larger model provided with an electro-magnetic steering device capable of being actuated by the wireless transmission of electrical action has been constructed It is housed in the Science Museum South Kensington

(To be concluded)

The Effects of Bends on Electrical Conductors

In a short article in the *British Westinghouse Gazette* Mr P Jackson discusses the effect of bends and loops on the inductance of a conductor It is frequently stated that the leads to and from apparatus—a lightning arrester for example—should be as straight as possible because short corners angles etc introduce an undesirable amount of inductance This, Mr Jackson contends is not strictly true. The only reason for avoiding corners and bends, he points out, is that a crooked line cannot be the shortest one between two points In fact, no matter how crooked and intricate the path afforded by a conductor, so long as one loop does not lie over another its impedance cannot be greater—and is in fact somewhat less—than that of the same conductor stretched out straight. Those who have been in the habit of looking upon loops and bends as

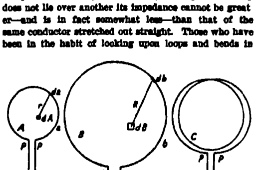

Fig 1

conductors as detrimental from the point of view of low inductance may feel inclined to reject this statement, but in support of the argument Mr Jackson puts forward the following illustration The inductance of a single turn of wire in the form of a circle is double that of a similar loop of half the diameter Consequently for similar loops the inductance is proportional to the length of the wire, in other words, the inductance is the same per foot of wire

If the loop be made very large, then a small section of it is approximately a straight line, and its inductance may be considered to be equal to that of a straight wire. Hence the inductance of a foot of wire carrying a given current is the same whether this wire forms part of a small loop or a large one or a straight conductor The diameter of the wire however has an effect which has not been considered and furthermore the statements do not apply to coils in which there are two or more turns For the statement to be strictly true the diameter of the conductor must vary with the size of the loop If not, the inductance increases slightly more rapidly than the linear dimensions of the loop

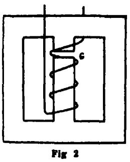

Fig 2

Neglecting this however the statements may be taken as correct. Assume that loop B in Fig 1 has twice the linear dimensions of loop A and of course an area four times as great. Suppose the area of A be divided into say 1 000 little portions dA and the circumference into a smaller number of short arcs da We can divide up the loop B into the same number of portions and dB will of course have four times the area of dA and db will be twice as long as da Now db being twice as long as da the magnetic effect of current flowing through it at any point will be twice as great Small elements also like dA and dB will be magnetically affected by da and db inversely as the square of their distances from one another

In general since the linear dimensions of B are twice those of A distance R will be twice as great as distance r and the magnetic effect of a given current in db on dB will be one half that of a similar current in da and dA However the area of dB being four times that of dA and its flux density one half as great it will contain twice the flux There being the same number of elements dA and da as there are dB and db the same conditions holds for the whole circles or loops of whatever shape so long as they are similar In other words the flux for a given current varies directly with the dimensions of similar loops and coils and the inductance is the same per unit length of conductor

Now suppose that loop B were many times as large as loop A so that a length of such conductor equal to loop A from p p would be practically a straight line Neglecting the influence of the size of the wire which was referred to above, its inductance would be the same as loop A Thus loop A from p to p has no greater inductance than the same conductor stretched out in a straight line In other words bends loops and corners are harmful only because they involve more conductor and not because such loops and bends in themselves increase the inductance But this is not the case if one loop overlaps the other as shown on the right of Fig 1 In this case the inductance increases in general as the square of the number of turns Sharp points are bad whether at bends of the conductor or elsewhere but for reasons due to the static rather than the magnetic field The production of magnetic lines around a conductor or through a coil by magneto-motive force is analogous to the flow of current through a resistance as the result of an electromotive force In one case the flow of energy is proportional to the value EI E being the pressure and I the current and in the other case the stored energy is proportional to the value HB H being the magneto-motive force and B the flux density With a given loop or coil if H be doubled by doubling the ampères B will also be doubled and their product or the stored energy will also be four times as great The same is true if the electromotive force applied to a fixed resistance be doubled—the energy input is quadrupled If a coil of given shape has the number of turns doubled the value of H for the same current is doubled and the magnetic reluctance remains the same so B is doubled and HB or the stored energy is quadrupled In this case also, as the stored energy per unit current is quadrupled the value of L or the coefficient of self induction which is a measure of this value is correspondingly quadrupled

This fact that the stored energy is proportional to HB develops another fact which is sometimes unsuspected. Take a coil such as that shown in Fig 2 with an iron flux path. If there is no air gap the flux per unit current is greatest, but the stored energy for a given flux is not. If an air gap G be introduced the value of H must be largely increased on account of the reluctance of the air gap The stored energy HB then becomes correspondingly greater If the coil is in a series relation to the circuit it is most effective if the air gap G is just large enough to permit saturation of the iron circuit.—*The Engineer*

The Future of the Police Arm*

Considered from an Engineering Standpoint

By Henry Bruere[1]

The author states as his reason for a discussion of the problems of police administration at a meeting of mechanical engineers that the most neglected field of public service in America is the police department. There is no part of municipal administration not itself in the engineering category that more urgently needs the aid of engineering methods than does the police arm. He makes this assertion on two assumptions with which he says there may not be general agreement. The first assumption is expressed in a definition of the substance of the engineering method. The second assumption is expressed in a definition of the functions of the police arm. These definitions are as follows:

a. The engineering method consists of applying scientifically determined knowledge to the execution of a particular problem and the use of ordered and analyzed facts as a basis for formulating conclusions in respect of that problem. As a result of the repeated application of the engineering method to like or similar problems a technique is established for achieving a particular object repeatedly with least waste of energy and resource.

b. The function of the police arm of government is to ascertain all the facts regarding the phenomena of crime and disorder and by the use of those facts as a basis for action direct and collateral to minimize and extirpate crime and disorder.

In respect to the functions of the police arm the author says that generally until now the functions of the police have been assumed to be something as follows:

a. General enforcement of certain laws and ordinances.

b. Enforcement of certain other laws and ordinances selectively according to the feasibility of their enforcement and the state of public opinion regarding them.

c. Enforcement of certain other laws and ordinances on complaint of persons injured by their infraction with particular respect to the perpetrators of the injury.

d. Repression or prevention of crime and disorder by the process of tacit intimidation. In other words the brass buttons and swinging night stick.

e. Physical and militaristic suppression of express disorder such as riots and street brawls.

f. Investigation of crime committed for the purpose of tracing, identifying and apprehending the criminal.

g. Performance of inspections, regulation of traffic, rendering aid to citizens and miscellaneous other incidental functions that are committed to the police as matters of convenience and are not generic to the police problem.

The one common ideal of police service that has been developed in American cities is that the police must be physically well-conditioned and personally honest. This is about as far as any American city has gone with the possible exception of Toledo under the rule of Brand Whitlock and New York city to-day under the administration of Mr. Mitchel and Mr. Woods.

In the minds of the conventional police criminals divide themselves into four groups:

a. Aliens, enemies of society violating the rights, safety and peace of a community, to be put away, thus gotten rid of.

b. Native incorrigibles endowed with natural perversity, namely the familiar thug, the gangster, the crook.

c. Fortuitous criminals who become subject to police action because of moral lapse or temporary aberration.

Or as belonging to

d. A miscellaneous group including special and individual cases too numerous to catalogue but comprehended generally in 174 items of the standard crime classification as used, for example by the New York police.

There has been no recognition of crimes as the consequence of remediable social conditions or the effect of individual abnormalities either physical or mental resulting from removable causes.

There should however, be a statistical basis for police work as there is a statistical basis for engineering work. There is nowhere in the world a collection of social data so potentially useful to the development of a community as lie in every great municipal police department in the records of arrests, in the records of crime disposition, in the investigation of crimes, in the note-books of policemen and in the memoranda and reports of detectives.

In the report of the New York police department for 1913 the only reference to these records is found in a single sentence under the heading Bureau of Records:

During the year 1913 there were received and filed in the Bureau of Records a total of 35 013 documents.'

New York city employs 11 000 policemen who made 119 736 arrests in 1913. It has a detective bureau of 150 detectives who investigate 55 000 cases of crime a year, but it has not a single employee engaged on an analysis of the facts brought into the archives of the department in the form of reports on investigations and records of arrests. Commissioner Woods is the first police commissioner in America, so far as the author knew, who has thought it worth while to put in his budget a request for statisticians. Next year he will have a statistician under the supervision of a deputy trained in statistical analysis who will study current police conditions and police work. Not only is he taking this step but he is utilizing every member of the force as an agent for gathering social facts respecting such matters as unemployment, destitution, improper guardianship, upon which intelligent police work must be predicated.

While it is generally known that economic distress and unemployment lead to an increase of small crimes against property and the breakdown of natural self-control, no American police department has ever analyzed its records to correlate degrees of unemployment with perpetration of crime and thus furnish the basis for police activity with regard to unemployment. New York city, however, has had this matter forced upon its attention. Conditions of unemployment last year furnished the opportunity for anarchistic agitation, demonstrations of violence, invasions of churches and other disorderly practices on the avowed theory that only in this way could the public be brought to realize the crucial importance of unemployment conditions.

These violent manifestations of disorder which had their relation to conditions of unemployment occurring in 1914 make it seem a natural function of the police to ascertain the facts regarding conditions of unemployment in 1915. The police department is the logical agency to call the attention of the community and other branches of the government to the need for taking some constructive steps to mitigate abnormal unemployment.

In New York one of the principal problems confronting the police is control of traffic. It was never conceived by the builders of modern cities that thoroughfares intended for residential purposes and often crowded with children would be utilized by high-powered motor trucks and automobiles and that many streets designed for local traffic would become the thoroughfares of a vast population. As a result of this condition there are killed each year in the streets 445 persons.

It is peculiarly the function of the police department to work out means of preventing this appalling condition, because the police department is charged with responsibility for regulating traffic. Up to January 1st of this year New York city's police did not record information necessary for an intelligent analysis of the conditions surrounding the death of persons in the streets although they are required to report the facts regarding each occurrence as a part of the coroner's investigation.

By focusing the attention of police captains and patrolmen on the incongruity of using congested traffic streets for play spaces for children, the present police commissioner obtained from patrolmen and their officers suggestions concerning the use of vacant lots for play purposes and for closing to traffic during certain hours of the day streets used by children for play. The mere fact that the police themselves formulate such suggestions and assist in putting them into effect, brings about a psychological change in the attitude of the policeman to his community relationships which is full of the greatest possibilities for the development of police service. It is merely another illustration of applying the scientific or engineering method to a particular problem, instead of continuing along from generation to generation with fatalistic resignation to whatever may happen.

The author anticipates possible criticism of his suggestions that they overlook the necessity for dealing with criminals as criminals and maintaining law and order by vigorous police action. It is no part of this suggestion that law enforcement be relaxed. A sentimental attitude towards breakers of the law and violators of the public peace and social rights of the community is not advocated. On the contrary, a very drastic action is favored regarding them where such action does not defeat its own purpose. It is recognized that the existing product of social environment, of disease, of mental degeneracy, of moral perversity, cannot be dealt with through eliminating conditions which breed them but have to be dealt with through our penal machinery and will probably sooner or later, for the protection of society, become the subject of police action.

A very considerable part of present criminality can be eliminated by intelligent preventive action. This preventive action should be initiated if not actually taken by the police. To initiate it intelligently, the police must act not on general information or impressions but on carefully gathered data. These data will not in every instance point to clear conclusions or be capable of definite analysis. The work of correlating crime to social conditions is practically untried. If law and order be at the basis of industry, if social adjustments are essential to economic welfare and civic development then no section of the community can ignore the police problem. It is particularly important that engineers who are the expert advisers of our industrial and economic life should make their special experience available to police administrators in formulating a method for arriving at the facts underlying the police problem.

The latter part of the paper deals with police organization. Involved in this are questions of training of officers, selection of officers, ratings for efficiency and selection for promotion, enforcement of discipline, methods of compensation, welfare activities, including educational work, medical supervision and provision for insurance and pensions. These various questions are discussed briefly. The author says further:

The outstanding fact regarding conventional police organization is that it is military and the outstanding fact regarding military organization is that it is not intended to accommodate itself to shifting social development, to relate itself intimately to community life, to be sympathetic and understanding or to be flexible. Military organization deals with individuals as subservient members of a group and not as self-governing factors co-operating in the execution of an undertaking. In police departments it has aimed at the one consideration everywhere recognized as fundamental in police work, namely personal integrity. The military assumption of moral and mental dependence of subordinates on superior officers has, however, been one of the great weakening forces of police work. In the case of policemen personal integrity results from exercise of self-restraint in inhibiting an impulse to accept a bribe to connive at a violation of the law or to practice extortion. The faculties needed to resist temptations of this character must be developed through a process of self-reliance, through a formulated, even though rudimentary, philosophy of personal conduct. The soldier ceases to be responsible for his moral conduct once he places himself under the command of a superior officer. This condition while of course less marked in police service than in a purely military organization, still prevails to a certain degree, and has been a conspicuous embarrassment to the development of individual police initiative in larger American police departments. Mr. Woods, New York's present police commissioner, has no military training or sympathies, and is dealing with the officers and men of his department on the assumption that they are self-controlling and self-initiating centers of police thought and police work. This method is a promising contrast to the policy of the martinet, or a policy of easy tolerance, that customarily prevails in police work, and stands out against the old conditions as strikingly as the modern, enlightened employer's policy in industrial management does against the old time shop boss method of dealing with workmen.

The future development of the police arm, if police work is to be constructive and to fulfill its possibilities, must be along the lines of the engineering method. The police department through its multitude of agents is the best equipped of all social agencies for apprehending sympathetically and certainly those adverse social conditions in the community which can be remedied only through community attention. The police department should be the eyes, ears and feeling fingers of the city government. If it finds through its investigation and observation that repressive facilities are inadequate,

*Abstract of paper and discussion presented at the Annual Meeting of the American Society of Mechanical Engineers, and published in their Journal.

[1] City Chamberlain, Municipal Building.

that this bears upon crime conditions and the welfare of the city's youth those facts should be driven home to the educational and recreative departments and in the same way with other conditions

The police department of a great city should be the nerve center of the city's government capable of acting with vigor when a situation demands vigorous treatment, strong to protect the safety of the public against disorder and the unruly informed on conditions which manufacture crime and criminals in order that these conditions may be remedied where remedies are possible, aggressive instead of defensive courageous instead of fatalistic organized for achievement instead of for mere opportunism, militant but not military except in the sense of obedience to necessary rules and responsive to discipline free to deal honestly with conditions in the light of those conditions instead of in the light of statutes written by dead hands co-operating intelligently with charities corrections, health hospitals and educational departments

To bring these things about the police problem must be broken up into its proper functional divisions Crime when perpetrated by professional criminals must be dealt with differently from crime committed by those who stray temporarily from the paths of rectitude There should be organized a national service for the detection of criminals and crime prevention along the lines of similar service now engaged upon forestalling and detecting counterfeiters The voice of the police department must be heard in the courts when punishment is meted out to criminals not because it is the police department but because it is informed and expert on questions of penology

Above everything else back of police work there must be developed a scientific spirit the true engineering spirit in place of cunning and cudgels there must be substituted a policy based upon a knowledge of needs standards of service feasible of attainment and organization devices to accomplish them methods of administration and the plant to facilitate their accomplishment and the genius to capitalize the initiative and individuality of every man on the force

DISCUSSION

Clement J Driscoll Bureau of Municipal Research New York city in a written discussion said that the cause for police inefficiency in New York can be found in the fact that in 13 years the department has had ten police commissioners Not one of these doubted the efficiency of the engineering methods and not one did not fully realize before he retired or was forced to retire from the department that the police problem was such that only careful patient application of scientific methods would solve it All of them would say to the engineers gathered here that all the methods known to science would be of little value while the control of the department was in the hands of the political powers of a community The Panama Canal one of the supreme engineering feats was made possible only because the engineer in charge remained on the job long enough to work out the engineering problem But even Mr Goethals would not have mastered the police problem of New York by the application of the engineering method if he had been subjected to the conditions under which all the administrative heads have had to work No matter how determined a police commissioner may be to keep his department free from politics it will be subjected to a political influence so long as he himself is subject to arbitrary removal and the mayor of a city is held responsible for a police department

In summarizing he urged as the first step toward increasing the efficiency of the police the adoption of statutes providing for a more permanent tenure of office for the administrative head second the complete separation of the police department from the mayor's office placing the full responsibility for the administration and conduct with the police commissioner or administrative head regardless of his title third the application of the engineering method and fourth the complete abolition of the system now in vogue throughout the country of adopting policies of law enforcement which will result in the enforcement of the statutes as written

Thunder*

Theories, and Experiments Conducted in an Endeavor to Solve the Problem

By Dr Wilhelm Schmidt

ATTEMPTS to explain thunder and lightning have heretofore generally been based upon a study of electrical sparks in the laboratory Although much valuable information has been obtained in this manner we should be cautious about assuming that the results deduced from such experiments apply to the gigantic operations of nature as it is easy to overlook factors that occur in one case and not in the other For example the discharges occurring in these laboratory experiments are generally oscillatory and it has commonly been assumed that the same was true of lightning discharges However Dr B Walter of Hamburg with the aid of his rotating camera has obtained convincing proof that lightning is mainly unidirectional A lightning flash begins with a preliminary branching spark that penetrates only a short distance along the ultimate path of the discharge this is followed after a brief interval (of the order of 1/100 second) by a somewhat longer discharge etc until finally a path is built up for a complete discharge which again is intermittent in character An even more striking proof of the difference between laboratory experiments and actual lightning is seen in the fact that the question of protecting buildings from lightning still remains unsettled opinions differing both as to the possibility and method of securing protection

In a like manner the conception of thunder as merely a reproduction on a large scale of the crackling or detonation of the sparks used in the laboratory needs to be confirmed by a study of the natural phenomenon more especially as very few attempts in this direction have hitherto been made In this study we may take as point of departure two important facts viz the brief duration of the phenomenon and the great accumulation of energy in a small space that it involves

On account of the latter there is a strong repulsion of electrified air-particles of like sign and therefore a sudden increase of pressure in the path of the spark H Mache and E Haschek have found a pressure of more than 60 atmospheres in the case of a spark 3 millimeters long, though this was in part the result of the vaporization of material in the electrodes A wave set up by this increase in pressure spreads out in all directions This is not an ordinary sound-wave as the fluctuations of pressure are not small in comparison with the normal pressure, but a so-called "explosion wave such as is observed in certain rapid and violent chemical reactions Such explosion waves, which we perceive as a report spread with a velocity that may be much greater than that of ordinary sound-waves, but are transformed into the latter as their intensity rapidly diminishes, owing according to Tumlirz, to the separation from them and lagging behind of secondary waves Experiments of Mache with "schlieren" and interference methods in connection with electrical sparks show plainly the sudden initial push, a condensation of air, then a longer and feebler wave of rarefaction, and finally, in some cases, a number of smaller waves

To assume that the same conditions apply to thunder, recognizing merely a greater intensity of the phenomenon, is not admissible without some further investigation, as in this case it is only rarely and under exceptional circumstances that we hear an actual report which is the distinguishing mark of an explosion wave Direct investigations of thunder are therefore necessary

For this purpose we have used two forms of apparatus one for the analysis of regular sound waves and the other for that of the longer pressure waves The former a modification of Marbe's apparatus [1] records the atmospheric impulses in the form of fluctuations in the deposit of soot from a flame upon a rapidly moving strip of paper The latter registers the displacements of an extremely light disk which hangs before an orifice opening into a box enclosing a large volume of air these movements are magnified by a suitable mechanism and the apparatus is provided with a time-scale Both instruments were kept ready for use so that registration could begin as soon as a thunderstorm occurred

The records from these devices showed that regular trains of waves of uniform length practically never occurred and hence that the thunder had no proper tone but was merely a noise and the records also showed that it was quite similar in character to the rattling of window panes The irregularity of the waves was greatest during the heaviest part of the thunder—i e at the moment of the clap—while toward the end of the thunder in many cases a certain degree of regularity was noted A statistical analysis of the frequency with which waves of various lengths occurred showed a preponderance of those lasting 1/40 second or more and again of those lasting between 1/120 and 1/75 second (i e vibrations of such length that if they had occurred in uniform trains they would have produced the tone F_1 or lower or again tones between D and A) Shorter waves most common in music were much rarer

The records of the second piece of apparatus showed that the greater number of the longer waves are in fact so long that they are imperceptible to the ear Their duration was mainly between 1/10 and 1/3 second in one case the duration was 0 54 second

The fluctuations in air-density occurring in connection with these waves were far greater than those occurring in ordinary sound waves or in the more rapid audible waves pertaining to thunder (Vibrations at the rate of 20 to the second may be assumed as the lower limit of audibility) Although the lightning was never near at hand—the interval between the flash and the beginning of thunder being mostly about 5 seconds—the records showed pressure fluctuations amounting as a rule to more than 0.01 millimeter Hence the greater part of the total energy of thunder is represented by these long inaudible waves which must be regarded as the essential part of the phenomenon and thus strange as the statement may sound, we may say that one really hears only the smallest part of a clap of thunder Most of the phenomenon either escapes our senses altogether or is perceptible only through the vibration of objects around us the rattling of window-panes etc In the immediate vicinity of the electrical discharge these pressure fluctuations are evidently, extremely violent, and a great part of the purely mechanical injuries wrought by lightning must be ascribed to them

The number of these violent waves is however never large In most cases they occur in irregular series of three or four in various parts of the thunder In the heaviest thunderclaps perceptible as such to our senses where the waves have generally traveled only a short distance and reach us but little modified there is usually but one violent wave viz at the very beginning Here we have complete agreement with what has been said above about explosion waves and from this fact we may draw certain conclusions

We are to conceive of a shock wave (*Stosswelle*) as traveling in all directions from the path of electrical discharge The prolongation of the phenomenon depends in the first instance upon the fact already mentioned that the discharge is frequently intermittent and may therefore set up several initial waves but more especially upon the occurrence of shorter audible waves which separate from the initial waves gradually increasing the magnitude and duration of the disturbance at the expense of its intensity The duration is further prolonged by reflection—not so much from clouds and sheets of falling rain as from the interfaces between atmospheric strata of different temperatures—and especially by the action of the wind The original sharp report is transformed into a roll or is sometimes divided into two or more claps Irregular short waves which give the rattling noise of nearby thunder are gradually lost in the more regular waves so that in distant thunder the sound may assume a more or less definite pitch

Whether the energy of the electrical discharge alone is sufficient to produce these phenomena is a question that can be answered without difficulty The energy of thunder as shown by the analysis of our records amounted in a maximum case to 22 000 kilogrammeters and was therefore very great compared with that of ordinary sounds In this case the thunder lasted 13 seconds and it would require more than 200 000 000 buglers blowing for the same length of time to produce an equivalent amount of energy Nevertheless this amount is insignificant compared with that of a flash of lightning for which we may assume and not in extreme cases something like 10^{10} kilogrammeters In fact only a small part of the energy of lightning is transformed into pressure-waves and sound most of it assumes other forms such as those of heat and light

We have still to consider the question of the rolling of thunder as related to the length of the lightning path In connection with the common idea that the sound reaches the observer first from the nearest part of the path and last from the most distant part and that the duration of the thunder depends upon the resulting interval of time the following facts should be borne in mind Assuming as a first approximation the case of a uniform impulse along a path free from sharp angles we shall have only a single wave spreading in all directions and the observer will perceive only a single brief sound whose time of occurrence will depend upon his distance from the nearest part of the lightning-path This follows directly from the Huyghenian theory of wave-motion Moreover bends in the lightning path will account only for a limited number of claps and not for the "roll" of thunder.

NEW BOOKS, ETC

UNIVERSAL SAFETY STANDARDS A Reference Book of Rules Drawings Tables Formulæ Data and Suggestions for Use of Architects Engineers Superintendents Foremen, Inspectors, Mechanics and Students By Carl M Hansen, M E Compiled under the Direction of and Approved by the Workmen's Compensation Service Bureau New York New York Universal Safety Standards Publishing Company 1914 12mo 312 pp illustrated Price $3 net

The earlier edition of this work was so well received that it is now issued in a revised and enlarged form embodying suggestions applicable to special industries Of the four divisions of the work the first summarizes general safety standards showing by lavish illustration their application to plant and machinery Part two takes up the machine shop part three the foundry while the final division suggests rules and practices for employees The method of illustration followed is to show the machine or part in black-and white line drawing with the safety device in vivid green Thus the eye is at once led to the source of danger and to the means of guarding against it By the co-operation of employers and employees along the lines laid down in this work very large percentages of human injury and economic waste might easily be averted

UNIT PHOTOGRAPHY By Frank Morris Steadman New York D Van Nostrand Company 1914 8vo 160 pp 13 plates 10 illustrations Price $2 net

Mr Steadman's researches seek to place the practice of photography upon a more scientifically exact basis He points out that fundamental elements such as the chemical energy of light the relative aperture of a lens and the sensitiveness of emulsions still lack simple units of measurement When such amateur work as is given over to the professional for development records a complete failure in from 70 per cent to 80 per cent of exposures any system that will materially reduce these failures should be welcomed The author suggests such a system in what he has termed Unit Photography in which he takes up the determination of units of measurement of light cones and of their photographic intensity and considers the character of photographic emulsions and the speed of plates His theories and methods are thoughtfully presented and should substantially contribute toward establishing both amateur and professional photography upon a more accurate footing

POOR'S MANUAL OF RAILROADS OF THE UNITED STATES Forty-eighth Annual Number New York Poor's Railroad Manual Company 1915 8vo 2060 pp Price $10

This valuable annual publication deals in an authoritative manner with the entire railroad business of the United States and Canada, also Central America and Mexico Details are given as to the trackage owned acquired by lease proprietary lines electric lines boat lines, etc as well as a complete history of the various roads the rolling stock, general income additions and betterments comparative operating statistics dividends capital stock transfer agents funded debt quoting debt board of managers and officers Thus for the New York Central and Hudson River Railway Company and controlled railways we find 104 pages devoted to this system. Excellent maps are scattered throughout the book. The amount of information which it contains make its compilation a vast undertaking This is a very handsome piece of book making

THE WORLD ALMANAC AND ENCYCLOPEDIA 1915 New York Press Publishing Company Price 25 cents

To attempt in the limited space at our command a description of that treasury of statistics known as the World Almanac would be vain as it would be needless Everyone knows its wide scope, its great fund of accurate information, and everyone turns to it for the support of their arguments and the settlement of disputed questions. With all the usual tables brought as nearly as possible down to date and with many new and vital subjects included it should extend still further its circle of friends The field of scientific research religion politics education athletics financial and national defense—to name but a few of the zones of human interest it invades—are ably covered

INSTALLING EFFICIENCY METHODS By C F Knoeppel New York The Engineering Magazine 1915 4to 258 pp illustrated

In this very attractive addition to the Works Management Library the author assumes that others have ably established the desirability of the higher efficiency he contents himself with describing the actual methods employed and their practical working out The volume begins like a novel We find the Enterprise Manufacturing Company in difficulties the employment of an efficiency engineer is suggested, and the suggestion carried in the face of strong opposition The way in which the expert attacks the problem and the consecutive steps taken by him to eliminate friction and lost motion in the organization, the management, and the men, are described in a happy blend of bright, attractive exposition with shrewd diagnosis and sound remedial [illegible]. These practical working [illegible] and explanations should prove invaluable to the owners and managers of non-modernized undertakings. It is impossible but that they should find much in the work that is applicable to their own problems and to some extent dissolvent of their own peculiar difficulties.

THE CUTLERS OF THIERS.—[See page 184.]

Modern Ideas on the End of the World*

New Contributions to Cosmology Obtained from the Development of Differential Theories

By Gustav Jaumann, Professor of Physics at the Technical High School at Brunn

We are totally ignorant of the beginning of the world. During the last century the hypothesis of Laplace and Kant that the planets proceeded from the sun and were constituted by the condensation of it enjoyed wide credence. According to this theory our earth was once in a state of glowing liquid. Judging by the increase in temperature in the deep strata it is covered at the present time by the solidified crust relatively very thin on which we live. Such a conception has rendered plausible a belief in the deluge and in the idea of a final day of judgment when the world will be devoured by flames.

Geology indeed records horrible catastrophes: the highest mountains were formed by a single short earthquake of tremendous violence the result of upheavals of granitic magma. By enormous volcanic eruptions erratic blocks were carried thousands of kilometers. In particular the whole of Asia suffered the invasion of the Indian Ocean which was precipitated on the continent with inconceivable violence sufficient to carry the rhinoceros and the mammoth which are considered Indian animals as far as the frozen fields of Siberia. Cuvier affirmed not only that the world would be destroyed some thousands of years hence but that it has already many times undergone like cataclysms, each geologic formation constituting the burial place of a creation entirely separate in origin. According to this hypothesis the termination of each geologic period has been marked by a complete ending of the world and the opening of each succeeding period by a special creative act giving birth to a new fauna more perfect but equally incapable of evolution. By the side of the brilliant Cuvier lived obscure and unknown the much greater Lamarck. It is he who recognized the continuous evolution of the faunas in accordance with an immanent law or at least in consequence of the capacity which organisms possess of perfecting themselves by assiduous exercise and by communicating in part to their descendants the improvements thus acquired. It is this way of thinking which after a turn toward Darwinism[1] has finally established itself. Now to permit such an evolution of the organic world from the beginnings to its actual perfection requires a considerable duration of cosmic quiet. Geologic investigations since Lyell have indeed demonstrated that the passage from each geologic formation to that succeeding it is made gradually and without interruption. The inundations and volcanic catastrophes which are produced at all times far from destroying worlds have never been more than purely local. Volcanic eruptions are not the index of a fluid and incandescent nucleus for the accumulations of liquid lava have little extension so that even neighboring volcanoes such as Vulcano and Stromboli have no relation to each other. One can even affirm that the fluid incandescent nucleus of the earth does not exist. Recent physical observations especially those relative to the transmission of the transverse seismical waves through the interior of the earth and to the period of migration of the terrestrial axis admit of the conclusion that the earth in its entire mass is as elastic as a steel of good quality.

But now we must observe the very disquieting previsions of the exact sciences. These we must notice particularly for physics and astronomy have exact natural laws and in this way may be predicted in all probability the most distant consequences for the laws which are concerned here that of gravitation and that of the conservation of energy are among the ones most firmly established.

The real achievement of Newton was to show that the law of gravitation had a more exact application than the laws of Kepler according to which the planets move along their elliptical orbits.[2] In reality the planets do not describe strictly elliptical trajectories. The form and the position of these trajectories change constantly although with extreme slowness. The law of Newton affords an explanation of the greater part of these divergences, if the reciprocal attractions of the planets are taken into consideration. Taking these deviations into consideration, it is possible at present to calculate to within a few seconds the positions of the sun the moon and the planets a hundred years in advance. But to determine at a distance of millions of years the end of the Newtonian world enormous mathematical difficulties must be overcome; indeed, it is a matter concerning the problem of the stability of the planetary system and of calculating whether the disturbing influences weak but incessant, which the planets exercise upon each other will nearly counteract each other in time or will end by entailing the destruction of the planetary system.

Eminent scholars have always taxed themselves with resolving this fundamental problem relative to the stability of the world. Laplace and Lagrange showed, by means of an approximate calculation that the planetary system of Newton appeared to be stable. Poisson demonstrated that by further refining the calculation later epochs could be surveyed in which greater and greater fluctuations in the form of the planetary orbits were present. Finally Poincaré proved that by carrying the calculation to its limit a future time was disclosed in which the planets would experience unlimited progressive so-called secular disturbances and finally some of them would fall into the sun, and others lose themselves in the cold of cosmic space. Thus the planetary system of Newton has no stability no internal constancy. But the foregoing calculations were made on much too favorable a basis. Cosmic space can not be empty as Newton held. Since it can transmit light, it must be filled with a medium extremely tenuous and cold called cosmic ether. The extreme vacuum obtained in the laboratory cooled to —170 deg. Cent. presents a considerable viscosity which is only ten times inferior to that of the normal air.[3] Consequently the cosmic ether must oppose to the movement of the planets a very appreciable frictional resistance. They must continually lose energy of motion in addition to which the attractive action of the sun becoming more and more considerable the planets should describe orbits more and more narrow and should end in some millions of years by precipitating themselves into it. Thus again we have the igneous death of the earth. But that end would be preceded by the destruction of the terrestrial organisms all being menaced by death from the cold which would set in much earlier.

The energy thrown out with the sunlight is several billion times greater than the total interchange of energy which takes place on the earth. The sun gives off continually enormous quantities of it, and its supply, of whatever unknown kind it may be, must finally be exhausted. It would cool down more and more and our civilization after terrible struggles would meet with disaster more and more amidst the ever-present ice.

Thus the two fundamental physical laws lead, it is seen to essentially gloomy consequences, but, with all the respect that is due to their sublime results and to their precision, it is only right to ask whether they are really established with such ideal exactness as to enable one to draw conclusions applicable to epochs immensely remote and to comprehend the very plan of creation. Before accepting these consequences it will be well to submit these inexorable laws to a much more searching scrutiny. That the law of gravitation will not support an examination carried to [illegible] nearly all astronomers agree in admitting. The [illegible] striking deviation from this law is offered by the moon, which undergoes an inexplicable acceleration, not less than 6 seconds per century. An analogous anomaly, more marked and still more [illegible] has been recognized in the motion of Encke's [illegible] orbit of Mercury presents an inexplicable [illegible] rotation, attaining 44 seconds per century, and the eccentricity is not augmented with the rapidity which the law of gravitation demands. The orbit of Mars is subject to anomalies of the same nature, while the inclination of the orbit of Venus increases too rapidly by 10 seconds every century. Terrestrial gravity presents even from the point of view of direction, a diurnal and annual oscillation of a fraction of a second, which is not to be explained alone by the attraction of the moon or of the sun.[4] It is true that these are relatively small and isolated deviations, and that in general the law of gravitation suffices for the calculation of the motions of the stars with a sufficient approximation, always assuming that the cosmic ether is absolutely devoid of friction. This latter, however, is far from being accepted by physicists. When one considers that the periodic comets, even the smallest ones, apparently undergo no frictional resistance, that they are capable of penetrating the solar corona at a speed of 5,000 kilometers per second, without undergoing appreciable loss, one is obliged to admit that the law of gravitation is not sufficient, but that forces unknown, though hinted at by Kepler, act upon the stars in motion, and tend to offset the effects due to friction of the cosmic ether. It is a fact that no trace, however slight, of a beginning of the falling of the planets toward the sun, as the law of Newton predicts, has yet been shown. The same may be said of the cooling of the sun, which should follow in accordance with the law of energy. It was supposed for a long time to be self-evident that the climate of the earth had grown constantly cooler, but this idea has been entirely abandoned. Fluctuations less than 10 deg. Cent. on both sides of the mean temperature have often occurred, several times in Europe, thus placing these regions now under tropical conditions, and now under the conditions of the Arctic Zone. But from this point of view the most remote ages of the geologic history of the earth differ not at all from the present epoch. Glacial formations, extensive but not thick, have been found in early Cambrian strata.[5] At that time the temperature was not higher but lower than in our epoch, and more than a hundred million years have passed since then.

One can with difficulty admit of the existence in the sun of a supply of energy able to endure without appreciable decrease, for so long a time, the enormous expenditure due to radiation. The stability of the planetary system and the inexhaustible luminous power of the sun are, furthermore, to a certain extent verified by direct geologic observation.

How is it that the law of gravitation and the principle of the conservation of energy fail so entirely in their prophecy concerning the end of the world? What is the hidden defect of these laws which, as the foundations of physics, have given such magnificent results within narrower limits, and how can they be given an entirely correct form?

Regarding these really fundamental questions of theoretical physics, I find myself called upon to speak, in so far as they fall within the field of my own studies. I should point out, however, that [illegible]

[illegible]

---

* Inaugural address of the rector of the Imperial German Franz-Joseph Technical High School at Brunn delivered on October 20th, 1912. Translated from the German in the annual report of the Smithsonian Institution, published by the technical high school.

[1] In this connection we designate as Darwinism only that part of Darwin's teachings which originated with himself, not the evolution theory which is due for the most part to Lamarck but rather the theory of selection according to which there could not be any evolution of the organic world without the influence of selection in connection with the struggle for existence.

[2] The law of gravitation itself was not originated by Newton but by Kepler whose ideas exerted a powerful influence on Hooke, Halley and Fermat. It was first formulated mathematically by Wren whose physical work was otherwise unimportant. Newton only contributed proof of its correctness. Kepler originated the fundamental and extraordinary new conception: "Virtutem quae planetas movet, residere in corpore Solis" ("The power which moves the planets resides in the mass of the sun"—heading of ch. 33 in Kepler's "Astronomia Nova." See Jo. Kepleri Opera Omnia," Frisch's edition, vol. 3, p. 300). He also originated the idea of the field of gravitation in which the force diminishes with the distance from the sun and the idea of universal gravitation. Had Galileo's dynamics controlled Kepler as it did Huyghens, he would not have needed half his genius to have anticipated Newton's contributions to the subject.

[3] This extreme vacuum at —170 deg. Cent. has the modulus of viscosity 3×10^{-6} c. g. s. To overcome the resistance that the ether offers to our earth would require more than 150,000,000 horse-power. [illegible] must glow in the ether if their diameter be less than 50 centimeters. As a matter of fact, a glowing [illegible] has been observed at a height of some 750 kilometers (above [illegible] on September [illegible], 1900, reported by G. von Niessl in Verhandl. d. naturforsch. Vereins in Brünn, vol. 17, p. 215, 1878), and even in the [illegible] of the comets when approaching perihelion (where their velocity is greatest) clear indications of the glowing of solid bodies have been observed.

[4] [illegible]

[5] [illegible]

[illegible] is in a state of tension, and that the [illegible] of the [illegible] did [illegible] were propa gated [illegible] point, from one particle to the particle [illegible] adjoining it. It is thus that the electro[illegible] is always produced in ultimate particles situated in the [illegible] field, and its law is a differential law expressing the relation of cause and effect between the existing conditions and their causative predecessors of each ultimate particle of the space. It is from this [illegible] between all the ultimate particles of the [illegible] field in the so-called integral that the effects at a distance result. Maxwell established the laws of effect from point to point of electromagnetism (or differential laws of the electromagnetic field) which with an admirable simplicity not only explained the electromagnetic phenomena formerly known (which the laws of effect at a distance were equally capable of doing), but did much more, they predicted indeed the propagation of electric vibrations through space in the form of electromagnetic rays. The luminous rays appeared then as electromagnetic rays. Hertz obtained, with purely electromagnetic resources, electromagnetic rays of great wave length, and Marconi has utilized these same rays in wireless telegraphy. Thus it is that one of the greatest and most difficult advances in the theory, the transition from laws of effect at a distance to theories of effect from point to point, led immediately to a great technical advance.

At that time (more than 20 years ago) many physicists, Hertz and Mach in particular recognized that the real object of the theory was to explain physical phenomena by differential laws a task which seemed to pass much beyond the attainable, but it has been in large part satisfactorily performed[1] since at present the law of gravitation itself can be expressed in the form of a law of effect from point to point.[2] The end sought in this connection consists in dethroning the old corpuscular and mechanical theories still so full of vigor. The list of facts brought forth by the two contending parties increases in length from year to year and this struggle between phenomenalistic investigation and mechanical investigation is waged on a field of great extent, embracing almost the entire domain of the exact sciences. The combat centers around the question of the nature of light and of the cathode rays.[3] The new theory of gravitation is only a partial victory on the extreme wing, but by virtue of it we now have exact notions regarding the manner of propagation of gravitation through the cosmic ether. The anomalies of the field of gravitation compensate each other in cosmic space according to a law analogous to that which rules the irregularities of the distribution of temperature in a good conductor of heat. It is only for stars in repose that the Newtonian law of effects at a distance follows exactly from the differential law of gravitation.

Now the motions of the planets produce disturbances a kind of damming up so to speak of the field of gravitation in front of the moving stars giving birth to new forces of gravitation added to the Newtonian forces. Although very small it can be determined with precision that the most important among them has the same direction as that of the motion of the planet to which it is a stimulus. It increases with the speed of the planet and varies in inverse ratio to the distance separating it from the sun. These new forces of gravitation introduce into the planetary movements disturbances which can be calculated without difficulty and even cause the deviations from the Newtonian law which we have mentioned above. By them are explained the anomalous perihelic rotations accelerations oscillations of the vertical etc.—that is all the phenomena of gravitation without any being left over which the Newtonian law of effects at a distance was incapable of doing. These new forces of gravitation moreover give to the planetary system a physical stability of unlimited duration. They keep the planetary orbits in their present form not only in spite of the very considerable resistance due to friction of the cosmic ether but also in spite of enormous accidental disturbances. If a disturbance of this nature (which might be due for example to the passage in the neighborhood of the solar system of a fixed star imbued with a very rapid motion of its own) should be produced and modify entirely the form of the planetary orbits the new forces of gravitation would introduce into the elements of the orbits such variations that these planetary orbits would gradually return exactly to their existing stable form. Far from becoming dangerous the frictional resistance of the cosmic ether on the contrary helps essentially to make the planetary orbits stable. The greater this resistance the more considerable become the new forces of gravitation and the more obstinate the planetary orbits in conserving in spite of all the disturbances their stable form. Thus there can no longer be any question of the planets dropping into the sun. Far from being unstable far from tending toward a destruction more or less remote the planetary system is then established for a duration which estimated according to the ideas of time that we are able to conceive, may be considered as eternal.

The absolute validity of the principle of the conservation of energy is incontestable but its new differential form[a] leads in entirely new directions. The cause of the indefinite constancy of the temperature of the sun rises from the inevitable reaction of the differential law of gravitation on the law of the propagation or radiation of energy and in particular the differential law of the conduction of heat, established by Fourier. The forms of the two differential laws must be placed in opposition to each other in order when taken together to correspond to the principle of energy. The very considerable rôle which the mass of bodies plays as the cause of the concentration of the forces of gravitation demands a corresponding influence of the mass of bodies on the concentration of energy. To the radiation of energy called the flow of heat there corresponds a new flow of energy in the direction of gravitation. Thus the law of the conduction of heat established by Fourier is strictly applicable only to media of extremely slight density. In dense substances there must be a hitherto unrecognized concentration of energy and this is not an hypothesis but simply the balance of the system of laws of effects from point to point. All dense bodies should in consequence produce heat incessantly and spontaneously. All bodies are so many radiations functioning without loss although in very different and to us generally imperceptible degrees. Far from being in contradiction to the principle of energy this fact springs exactly from its expression in the form of the law of effect from point to point. The salts of radium indeed produce a similar effect of spontaneous radiation but this is of such an exceptional intensity that it has amazed the physicists. Upon its discovery doubts were conceived of the validity of the principle of energy but it is only the integral form of the principle which gives place to these doubts while the differential form or the law of effect from point to point is thus all the more firmly established. The increase of temperature in the deep strata of the earth is explained by this effect of spontaneous radiation without the intervention of the hypothesis of deposits of radium. Moreover there is produced toward the sun an enormous concentration of the new radiation of energy arising from the field of gravitation which compensates for the loss of energy which the sun undergoes and assures the permanent constancy of its mean temperature. Consequently the sun yields no energy at all to the wide circle of cosmic space that which it radiates into cosmic space is recovered in the form of this flow of energy from the field of gravitation. The senseless waste of the sun's energy of which the theory of effects at a distance seems to prove the existence is shown by the theory of effect from point to point to have no place in nature. A cooling off of the sun will not bring the development of our civilization to a stop after which through the deterioration of the climate it will disappear and the last men will live like Eskimos on the entirely glaciated earth. The radiation from the sun being stable the intellectual and physical evolution of humanity will be able for an immeasurable time to mount to heights surpassing perhaps anything the imagination is capable of conceiving.

Thus as a result of the development of the differential theories a new and unsought contribution to cosmology of high and moral also essential value has been obtained.

[1] G. Jaumann, A complete system of physical and chemical differential laws, Sitzungsber. K. Akad. Wiss. Wien Math Naturwiss. Kl. vol 120 pt 2a 1911 pp 385-530

[2] G. Jaumann, The theory of gravitation, Sitzungsber. K. Akad. Wiss. Wien, Math Naturwiss Kl vol 121 pt 2a 1912 pp 95-182.

[3] The majority of physicists still subscribe to the emission theory of cathode rays (the corpuscular or emissional theory) and there is a tendency under the leadership of Einstein and Planck, toward giving up finally the essential features of the classical theory and going back to a sort of emission theory of light.

Regarding the undulation theory of cathode rays and the phenomenalistic undulation theory of light in dispersion media see G. Jaumann, The electromagnetic theory (Sitzungsber. K. Akad. Wiss. Wien, Math. Naturwiss. Kl. vol 117 pt 2a, 1908, pp. 379-543) which paper was rejected by the editors of the Annalen der Physik in 1908 and in 1911 was honored by a prize by the Imperial Academy of Sciences in Vienna. See also E. Lohr, The boundary conditions in G. Jaumann's electromagnetic theory (Sitzungsber. K. Akad. Wiss. Wien Math Naturwiss Kl vol 120 pt 2a 1911 pp 1563-1567 and vol 121 1912 pp 653-678.

[a] G. Jaumann, Sitzungsber. K. Akad. Wiss. Wien Math Naturwiss. Kl. vol 117 pt. 2a p. 385 et seq. vol 120 p. 395 and p. 505 vol 121 p. 169

The Conditions of Industrial Accidents*

The enactment of laws in various States on workmen's compensation for injuries has aroused increased interest in the statistics and physical and psychic conditions of industrial accidents. The total number of these accidents is almost appalling. The lowest estimate places the fatal accidents to adult workers in the United States at 35,000 a year, with an additional [illegible] non-fatal accidents. The Massachusetts Industrial Accident Board, on the other hand, placed the number of workers killed by accident yearly at 75,000, which apparently includes not only adults, but also workers of all ages, while the number of injured of the same [illegible] was placed by this Massachusetts authority at [illegible] or over. An earthquake in a foreign country [illegible] kills [illegible] of persons and [illegible] of those injured in our United States [illegible].

[illegible] statistics of these accident [illegible] greater proportion of accidents [illegible] of the [illegible] fatigue. [illegible] should [illegible] contention though it has been disputed. In the Massachusetts Industrial Accident Board Reports in which the official figures are given there is scarcely more than one twentieth more accidents on Monday than on Tuesday while Tuesday is not much above the average in the number of accidents reported for other days. Saturday of course shows a noteworthy reduction because of the half holiday in some trades.

By far the larger number of accidents occur at about 10 A. M. and 3 P. M. This fact is confirmed by the reports of two State boards Washington and Massachusetts, which have secured rather careful records. As they represent the extremes of the country the conclusions from their statistics would seem to be incontrovertible, though the fact is not what might naturally be expected. The State of Washington Industrial Commission[1] says, "These results seem to disprove the theory that fatigue is the prominent cause of accidents because accidents are here shown to happen at the hours when the workmen are least fatigued." On the fatigue theory it might naturally be expected that most accidents would happen after 11 A. M. and 5 P. M. The actual hour of the high point of the curve of accidents shows how important are the facts and how necessary of proof the theories.

After much discussion, the tendency to speed up employment has been incriminated, as the predisposing condition for the occurrence of accidents. This desire comes over the workman when he is not yet fatigued, but has been employed for several hours. He starts the morning's work cold and as he warms to his work the danger of mischance because of haste becomes greater. Just when the speeding up reaches a climax in the morning hours most accidents happen. The same thing is true in the afternoon. Workmen feel sluggish after their lunch but after an hour of work warm up again and by about 3 o'clock they are doing their most rapid work and are at the same time more subject to accident.

With regard to accidents among children however there is no hour of maximum. Accidents occur at all times and they are comparatively much more frequent among children than adults. The United States Bureau of Labor reported that "there is clear evidence of great liability to accident on the part of children. Though employed in the less hazardous work their rates steadily exceed those of the older co-workers even when in that group are included the occupations of relatively high liability." This was said with regard to the Southern cotton mills but the same thing is true of practically all industries in which children are employed.

The results of these accidents come to the physician. We are devoting much time to the prevention of disease, and we should be ready to give attention also to the prevention of injury. Virchow used to say that the ideal function of the physician besides that of reliever of human ills, is to be the attorney of the poor for the prevention and relief of social ailments, and, above all the prophylaxis of their physical consequences, whether in lowered health or in maiming injuries.

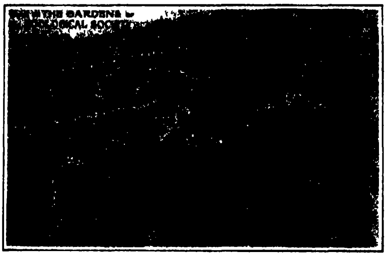
Gardens of the Zoological Society of London

Its History, Organization, and Its Valuable Collections

By R W Shufeldt

As is the case with all the achievements of man museums zoological gardens and aquariums have each and all had their beginnings Some of these latter have been of extremely modest pretensions while in the case of others the starting has been upon a far broader basis and the enterprise given an initial impulse through the influence of powerful patronage and munificent financial support which in any particular instance has at once placed the institution in the foremost rank with others of its class In the present article it is not my intention to have anything to say in regard to any museum or aquarium these subjects will be taken up later on but I propose to point out some of the advantages of a will soon be discovered that the most valuable of these date from the time of remotest antiquity Such tracing quickly carries one into the musty tomes of the fabulous ages where traditional history soon becomes obscure and the thread of investigation is lost In those archaic times collections of living animals were known as menageries and in the main they consisted of collections of large mammals (and sometimes birds) obtained by the monster-queller who for that purpose accompanied the armies of invasion in the days of ancient Greece and Rome These nations in many respects were barbarians in those days and most of us know of the brutal and fiendish uses to which these captive lions and bears affluence The later Cæsars were then in power, and during their regime, Pliny produced that very [illegible] and marvelous production—his work on the natural history of animals As we are now aware, every page of its reeks with error, or is rendered worthless through the flagrant introduction of the fabulous and the ridiculous.

But we are not concerned with these writings here, or with the extraordinary times during which they appeared, I aim but to refresh the mind of the reader with respect to the origin of menageries in ancient Greece, and the formation of the *vivaria* in early Rome. For fully fifteen centuries thereafter there was no building



Plan of the gardens of the Zoological Society in London

South entrance to the Zoological Gardens.

first class zoological garden and for this purpose I have selected the Zoological Gardens of London as my example

Let me say at the outstart that these Gardens belong to the Zoological Society of London an organization of world wide reputation which was incorporated by Royal Charter as long ago as the year 1829 having for its main object the advancement of zoological science—a mission which it has most efficiently performed for a period extending over three quarters of a century Personally I have always taken an active interest in the welfare of this Society and as I have been one of its corresponding members for nearly 30 years I am more or less familiar with its history the history of its gardens and with the enormous influence the two combined have had in promoting the best interests of the science of zoology throughout the civilized world While it did not receive its charter until 1829 these gardens were first opened to the public a year before that time or on the 27th of April 1828 This statement however will by no means enlighten the reader upon the highly interesting question of the origin of these gardens—a point I desire to refer to before passing to matters of a more recent nature

In order to discover how zoological gardens first came into being—if one be so fortunate as to ultimately obtain such information—it behooves the searcher to scan the historical records having reference to them and it tigers and leopards were put in the public arenas and in the dungeons of the cities of the conquerors

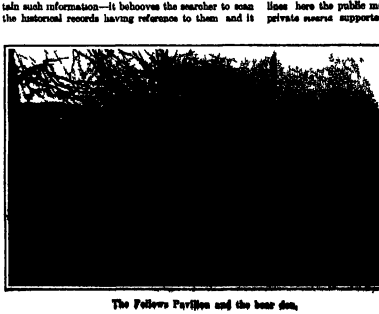
Still as the years passed by these very early nations with all their cruelty and barbarism in time presented the evidences of the dawn of thought and observation Individuals appeared from time to time who in an era of increasing leisure devoted themselves to philosophic studies of their environment and in this was included the wild and captured animals which came within their ken Sentimental as this movement was at first it speedily became the foundation for more exact zoological research and the dawn of scientific investigation set in

Thus it stood in later Greece when the Macedonian conqueror Alexander led his victorious armies eastward even to the very banks of the Indus Never did he allow an opportunity to pass through which he might further the aims of science or add new animals to the marvelous menagerie he had already formed at his native capital Aristotle his old friend and tutor took up the serious study of these treasures and reveled in the extensiveness of the undescribed material at his hand In due course it bore its fruit and the world was given one of the most original and greatest zoological works of the period Aristotle's *History of Animals*

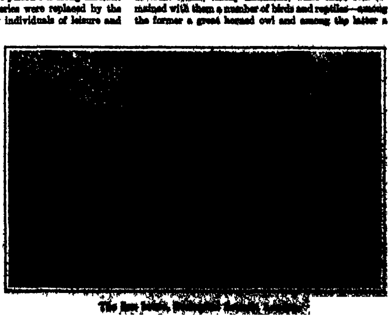
A somewhat similar growth of natural science took place in Rome during the same period but along different lines here the public menageries were replaced by the private *vivaria* supported by individuals of leisure and up anywhere in Europe of a menagerie or a zoological garden while the entire science of animal history was steeped in fable and shrouded in the rankest atmosphere of ignorance

It was not until Louis the Fourteenth founded and sustained a menagerie at Versailles that the interest in such institutions was again revived on the Continent, and writers once more appeared to take advantage of what was at hand for them—that is, a large and varied collection of captive animals, and such other material as the early museums there supplied. The *Natural History* of the highly imaginative Buffon followed, as did, about the same time, the far more exact work of Daubenton—respectively the Pliny and Aristotle of those later times

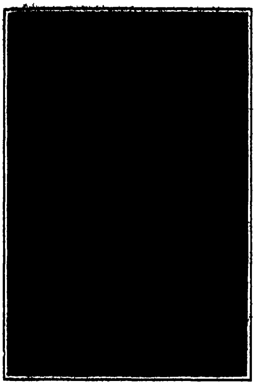
In London—very early London—was the Tower Menagerie which may be said to have been the ancestor of the present Zoological Gardens of the Zoological Society of London at Regent's Park This Tower Menagerie possesses a wonderfully interesting history, and one I may say, far too extensive to be touched upon in this article In 1828 there was an admirable collection on public exhibition there consisting of a large number of very valuable animals, some of which, later on, found their way into the present "Zoo" There were about sixty different forms, chiefly mammals, while there still remained with them a number of birds and reptiles—among the former a great horned owl and among the latter a



The Fellows Pavilion and the bear den.



The [illegible]



The white pelican

rattlesnake, these in evidence of the fact that even at that early day, upwards of a century ago wild forms were being obtained in America for exhibition in London.

The Zoological Society as now organized consists of nearly 4,400 Fellows and, taken together of some 300 Foreign, Honorary and Corresponding members There is elected annually a council which governs it and King George who has been a Fellow since 1894, is its patron The Duke of Bedford is its present president and its secretary is Dr P Chalmers Mitchell F R S At stated intervals it issues *Proceedings* and *Transactions* the latter being a sumptuous publication in which has appeared many of the most famous zoological contributions in the English language Reports upon the animals of the "Zoo" appear as a rule in the *Proceedings*

Among other buildings there is a fine library and offices at Regent's Park, which is located at No 50 as shown on the accompanying plan I may say in passing that all the views shown of the park and its buildings in this article were kindly made for me by Mr F W Bond F Z S the official photographer to the Society, who has a wonderful collection of photographs of animals which have been kept at the Zoo, all secured by himself

These London gardens occupy but a small extent of ground in the very heart of the city There are not over 34 acres in all, though the views would lead one to suppose that the place was considerably larger As will be seen by the accompanying plan the grounds have been admirably laid out, and that with the view of making the many inmates as comfortable and contented as possible, compatible with the economical apportionment of space As a property, these gardens are held from the Crown, through the Office of Woods and Commissioner of Works, at a fixed annual rentage

It is scarcely necessary to say that there is a distinguished staff of naturalists connected with these gardens, and a very large body of workmen employed to perform the many duties associated with such an extensive institution Some of England's greatest scientists have, in the years gone by, been connected in one capacity or another with the "Zoo," and the extent of the published researches made by them is one of the grandest monuments that has ever been erected to biological science.

Hundreds of animals of all kinds are upon exhibition there at all times, and the list of those which have been kept there in times past is not only enormous, but includes nearly all the forms known to us—that is, in so far as the vertebrates are concerned. Each year the Reports of the "Council and Auditors" are published, and [illegible] which [illegible] is to [illegible] For example, [illegible] Animals living in the [illegible] 1913 was 2,806. [illegible] December, 1913 [illegible]

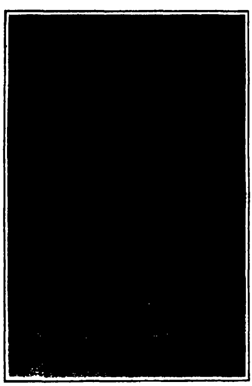
[illegible]

dia in the collection as well as researches upon their anatomy, both normal and pathological Mr F E Beddard, F R S is the present prosector and Mr H G Plimmer, F R S the society s pathologist An enormous quantity of excellent work has been done here which for years past has been published in the society s *Proceedings*

The admittance to these gardens is quite special as a charge is made for admission of one shilling for adults and a sixpence for children On Mondays however and on certain advertised days it is sixpence for every body and on Sundays the gardens are closed except to Fellows and their friends who gain admission with special tickets

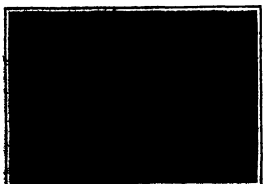
The society publishes an official guide-book which is not only beautifully illustrated with pictures of a large number of the animals—half tones from photographs—but it prints a great quantity of information about them as to their habitats habits in nature breeding and much else besides Some of these accounts are more extensive than one finds in works on natural history and certainly more trustworthy

Under the giraffe-house for instance (No 62) we read in this guide that The first living giraffe which is known to have reached England was sent to his Majesty King George IV in the year 1827 It lived two years and two months In the summer of 1836 four giraffes from Kordofan reached the gardens safely These succeeded in the most remarkable manner and no less than seventeen individuals were bred in the Society s gardens from these animals or their descendants In 1881 the last survivor of this stock died but the Society was able to purchase other examples and to exhibit them until the last died in 1892 At that time and for some years afterwards the Soudan was practically closed because

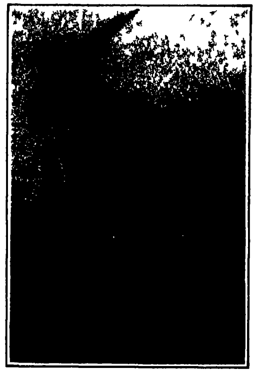


The Southern giraffe

of the rise of Mahdism and the next arrival was a fine young female imported from South-east Africa which however died in 1907 A pair of giraffes from the Egyptian Soudan was presented to the society by Col Mahon the governor of Kordofan in 1902 and from these was born in September 1907 a young female which has been successfully reared The coloring of giraffes from different localities varies very much and some naturalists believe that a number of species and



Pitaba, the Indian tiger.



The Beisa oryx

perhaps two genera should be recognized All the principal mammals and birds in this guide of over 100 pages receive such notices as the foregoing so that the body of information thus presented is both valuable and instructive

As I know from personal experience the Society is very glad to receive at any time living animals for its menagerie and these are invariably fully acknowledged in its annual report in the year in which donations of the kind come to hand I usually send such animals by express in properly constructed cages and I have thus succeeded in transporting different species of turtles horned toads an Arizona squirrel and so on The list of such donations during a year usually number several hundred from all sources Occasionally these are of unusual extent and correspondingly valuable as for example when the King last year presented the gardens with the Nepal collection consisting of 48 large and rare mammals and 1 birds while the Duke of Bedford and the government of the federated Malay states presented during the same year many animals of the greatest value

The installations of such collections as those at the gardens form occasions in which the royal family not only take part but greatly excite the interest of the public afterwards For instance in the case of the King s Nepal donation it is reported that The collection on board the British India Company s S S Afghanistan reached the Royal Albert Docks on May 20th and arrived at the gardens before 8 P M The animals were at once installed as all arrangements had been made for them and they were on view to visitors on May 21st The King and Queen and Princess Mary visited the gardens on the afternoon of May 31st to inspect the animals By the King s wish the visit was strictly private and no special preparations were made

As will be seen from Mr Bond s interesting photographs some of the views in the London gardens are very attractive and along the canal and elsewhere one can hardly realise that the places are in the very heart of the largest metropolis in Europe

The entire management of these gardens is carried out along strictly scientific lines and under a plan of management which appeals to anyone who appreciates extreme tidiness system and proper presentation of the animals he resorts there to study and such a one cannot fail to be encouraged by the knowledge that behind it all science is constantly utilizing the material through published papers and reports to the advancement of civilization and to the national credit of the country sustaining the institution

Efficiency of Coal and Electric Heaters

Concerning the importance of efficiency of electric and fire radiators but little general information has been given out In some recent experiments it is stated that an electric lamp radiator gave out 548 watts, against 1 060 put in, or an efficiency of 52 per cent. On the other hand a fire radiator produced 727 watts out of 1,570 put in, giving an efficiency of 46 per cent. There are, however other questions than those of comparative efficiency to be considered, as, for example first cost and cost of maintenance, which is undoubtedly greater in the electric outfit. The care necessary for operation and the space occupied are also often important.

A New Era in the Science of Nutrition

How Two Masters in the Art of Experimentation Are Bringing This About

By R. L. Kahn, M.S.

About four years ago, Dr. Thomas B. Osborne and Prof. Lafayette B. Mendel, began a series of feeding experiments at New Haven, which have had the high distinction of being epoch making from the very beginning. They have been epoch making because chemical analysis, physical measurements and mathematical precision underlay their procedure. These experiments are still being continued and the scientific world waits and wonders what these investigators will unearth next.

It is nearly 30 years since Dr. Thomas B. Osborne was appointed Research Chemist at the Connecticut Agricultural Experiment Station. His many investigations in the chemistry of foods during all these years, have given him a name equaled by few in the entire world of science.

Prof. Lafayette B. Mendel, although comparatively young, has occupied the Professor's Chair in Physiological Chemistry at Yale University for over 15 years, during which time he has gained enviable fame as a chemist of animal life. And to-day his laboratory is the Mecca for those students whose aim is to solve, by chemical means, some of the mysteries of animal life.

These investigators, with the assistance of Miss Edna K. Ferry, Dr. Alfred J. Wakeman and a host of chemists of the Connecticut Agricultural Station, made up a gigantic scientific-research combination, with the modest aim to clear new ground and extend the road of the unexplored territory in the science of nutrition.

MANY-SIDED EXPERIMENTS

The most important period in the life of an animal is undoubtedly the time of its growth, when its bodily foundation is being laid and the body structure built. These investigators showed us that Nature will not build an animal body if the supply of proper building material be withheld from the animal—if it be improperly fed. The young animal under these conditions need not be underfed; on the contrary, it may consume enormous quantities of improper or inadequate food; nevertheless, it will not become larger and gain in weight—it will not grow—as young animals should and ordinarily do.

The effect of nutrition on growth is, however, only a small measure of their far extended investigations. The rôle bacteria play in digestion, the importance of the inorganic constitutents in our diet, the relative nutritive value of different fats, such as butter and lard, and a number of other problems of practical concern to man, have been investigated by these workers. And when we consider the far reaching importance of these experiments it becomes clear to us why the scientific world has taken such an active interest in them. Efficient and economic feeding is not only of importance to man in his personal pursuit of health and happiness, but to the cattle raiser as well. Science is the greatest waste eliminator we have, and ultimately it will prove to be *the* important factor in reducing the high cost of living.

FORMER VIEWS

It is needless to say that experiments of this nature could not have been undertaken had we still believed that "the food we ate was first converted by the liver into natural spirits, which the blood and inspired air changed into vital spirits and which, on reaching the brain, became animal spirits." Neither would these investigations have been possible had we still thought that the meat (protein) we eat, became body flesh with very little transformation.

It was this latter view which led Justus von Liebig, the great pioneer in physiological chemistry, to suggest that the best food for one who works with his muscles is some other animal's muscle, such as beef. This theory could never make clear how the ox builds up its beef on a purely vegetable diet. We know now, beyond the slightest shred of doubt, that the energy required for muscular work is furnished largely by the carbohydrates (starchy foods) and fats.

Unfortunately the Liebig view is still popularly accepted. Again and again friends advise us to eat meat for strength, forgetting that our domesticated animals which display the most strength, such as the horse and bull, are herbiverous animals and live on a vegetable diet exclusively. This is not an appeal for vegetarianism. Man should eat meat, but let him eat it moderately and not entertain the idea that it supplies him with energy for muscular work.

The erroneous corpuscular theory of light, formulated by Sir Isaac Newton, which kept the world in darkness for several centuries, until the wave theory of light finally conquered, is a similar example in the field of science of a great man's error and its influence.

It is evident that, just as the helpful suggestions of the great exert a goodly influence, in the same way, and to the same degree, do their erroneous views exert their harmful effect.

THE PROTEIN MOLECULE, A HUGE STRUCTURE

The greatest interest in the study of nutrition attaches itself to the protein molecule; the nitrogenous molecule which goes to build up the various tissues of the animal body. The carbohydrates and fats are our coal foods; they furnish us with the same amount of heat and work energy which they would furnish an inanimate heat engine if burnt in it. But how the protein of a grain of wheat can be transformed into a nerve fiber, a drop of blood or a muscle cell, appeared until recently quite inexplicable. It was known for a long time that the grain of wheat was first broken down in the digestive system, after which the body would utilize the broken down products, to suit its own needs. Further than this, however, nothing was known.

Thanks to the recent laboratory investigations, we now know the chemical nature of the protein molecule better than we ever did before, and we can follow up its life cycle in the animal body with much precision.

The protein molecule, although physically not big enough to be seen with the highest magnification under the microscope, is, nevertheless, chemically a very huge structure. Should we break it up it will yield an enormous number of other molecules. These new molecules the German scientists have christened with an unusually appropriate name. They call them Bausteine (building stones), they being the building stones which go to make up the protein molecule. These building stones are definite chemical substances known as amino acids.

DIFFERENT BUILDINGS WITH SIMILAR BUILDING STONES

When a protein molecule is allowed to come in contact with acids or digestive fluids, the building stones or amino acids are liberated. These building stones can now serve as the material with which new protein structures, such as liver, brain and muscle protein may be built. This in fact, is what takes place during digestion. The digestive fluids liberate the building stones of the proteins which we eat. These building stones enter the circulation and are distributed to the different tissues of the body, where they serve as the building material with which the body builds new tissues to suit its own needs.

We can now understand how the lion in the jungle, the cow in the stall or the bird in the nest, can build up tissues which are so similar on foods so entirely different. The mystery was solved when the laboratory student subjected a large variety of foods to chemical analysis, and found to his great surprise that the building stones of the various proteins found in these foods were essentially the same.

Just as we have in any city a large variety of structures built with similar materials, we have in nature a large variety of proteins built with similar amino acids. Some structures in our city, embodying more building material, are larger than others; others, again, containing different proportions of certain building stones may vary in form or style. Similarly, some of our proteins lack amino acids, like gliadin of wheat and zein of maize, and are therefore smaller—or to use a laboratory phraseology—are incomplete proteins. Other proteins again, are believed to contain different proportions of certain building stones. Thus, for instance, albumin of egg and globulin of meat are two complete proteins; i. e., as far as is known, they do not lack any amino acids, still they possess different chemical properties. It is extremely probable, therefore, that these two proteins contain varying proportions of the same building stones.

The blood of the lion, cow, bird or any other animal, knows not whether the source of the building stones which come to it be a grain of wheat or a bit of flesh. This is not its business. It is the business of the animal to obtain food, that of the digestive system to convert this food into energy-yielding and tissue-building material, and it is the blood's duty to receive the daily supply of this new material, particularly the tissue-building material, or amino acids, and distribute it to liver, muscles and other organs of the animal body where it may be utilized to rebuild the cells which are being broken down in the daily wear and tear.

A VISIT TO THE LABORATORY

Let us now spend a few minutes in the laboratory where the experiments with which we are most concerned are being carried on. We are all sufficiently advanced in the science of nutrition to understand fully the work of our investigators.

Here we are in a large and dignified brick building on Huntington Street, New Haven. It is the newest building of the Connecticut Agricultural Experiment Station. We will enter to the right the spacious room on the main floor and watch the chemists at work. Practically all are busily engaged isolating proteins from various food stuffs. We see one adding an acid solution carefully to a 10-gallon jar containing milk. We can see the flocculent precipitate of casein being formed as he adds the acid. He is separating the casein from the milk. Another is isolating edestin from hempseed. A third is re-purifying the glutenin he obtained from wheat, and so down the line. Every one seems to realize the importance of his work, for these isolated proteins are to be used in the feeding experiments of Osborne and Mendel.

In another room we see several hundred cages, each about the size of an ordinary bird cage. In each of these cages one or more white rats are slumbering. These animals sleep during the day and are active at night.

The white rat serves as the experimental animal because of the relative ease with which it can be looked after, and also because the life cycle of this animal and its relation to man has in recent years been carefully studied by Prof. Donaldson at the Wistar Institute.

The duration of life of the white rat is three years. For 20 days after birth it will depend upon the mother for sustenance. It is sexually mature at the age of 60 days, and its entire growth period is completed when it is 280 days old. The first year of the rat's life corresponds to the first 30 years of human life, and, according to Prof. Donaldson, the 3-year-old rat is very old—comparable to the 90-year-old man.

MAINTENANCE AND GROWTH

To begin with, the diet of these animals consisted of starch, lard and inorganic salts to which was added some isolated protein. Soon our investigators established the fact that there is a difference between the requirements of a mature animal and that of a growing animal. The adult animal needs protein material with which to repair the daily wear and tear of its body; the growing animal needs protein material with which to build up its body. They found again and again that diets which were sufficient to maintain an adult animal in good health were not sufficient for a young animal to grow on.

This, in reality, is what we would expect. You cannot often build a machine with the materials with which you can repair it; and the food which can adequately repair the animal machine may not be sufficient to enable the animal to grow and build up its body. Nature set down more rigid food requirements for the young animals than for the mature ones, to make sure that the bodily foundation which the former build during their period of growth be of solid and strong material so that it will withstand weathering later in life.

Growth is, indeed, a very mysterious phenomenon in the life of an animal. The growth-impulse, or "*Wachstumstrieb*" as the German physiologists call it, is inherent in all animals. It appears to be a function of the young animal cell. Nutrition, no matter how rich, can neither hasten nor prolong growth; if inadequate, however, it will interfere with the growth of an animal.

UNDERFEEDING AND IMPROPER FEEDING

There appears, also, to be an important difference between underfeeding and improper feeding. If you underfeed an animal, that is, if what you give it is nourishing food but of insufficient quantity, you will not interfere with its ability to grow. Its growth, however, will be at the expense of its own tissues. The bones will enlarge, but the muscles and other tissues, not receiving sufficient nourishment, will waste away.

Should an animal be improperly fed, as is the case when you feed it with an isolated protein which lacks building stones, growth itself will be interfered with. Under these conditions, no matter how large the quantity of food the animal may consume, it will not grow.

Take for instance Rat 240. Its diet consisted of starch, lard, inorganic salts and gliadin, one of the proteins of wheat which is known to lack several building stones. At the age of 140 days it weighed only 55 grams, when it should have weighed about 150 grams. Now this animal did not suffer from underfeeding; it ate well and its energy requirements were fully supplied, nevertheless, it was unable to grow. It is fair to assume, therefore, that the lack of some building stones in its food prevented this animal from building up its body.

THE FRANCHISE TO MANUFACTURE BUILDING STONES

It has been known for a long time that an animal cannot live without certain specific food stuffs. An animal needs to have some carbohydrates with which to supply its body with heat and work-energy. It needs minerals with which to build its skeleton, and other inorganic salts to maintain the body fluids in proper chemical equilibrium. And, finally, it needs protein, or more

specifically, building stones, with which to build the animal machine.

Withhold protein, carbohydrates or inorganic salts from the diet of an animal and the animal cannot live. However, feed an animal with a protein which lacks several building stones and it will live, but will not be able to grow.

This is very remarkable. Nature starts out an animal in its struggle for existence with the most abundant equipments for life. All its organs contain far more material than it actually needs. More than half of its liver and pancreas can be removed with impunity. Remove a lung or a kidney, or let an animal lose more than half of its blood, and still the animal will have its health. Nature provided the animal with every conceivable means to continue its life in the midst of adversities. However, the franchise to manufacture building stones nature granted almost exclusively to the plant kingdom. And if you withhold building stones from an animal's diet the workers of the animal machine will lay down their tools. Work will stop. The animal structure will not be built.

Supply plants with the raw chemical elements, such as carbon, hydrogen, nitrogen and so on, and sunlight, and the most complex structures will be built by them. Animals can not do this. The digestive systems of animals can only break down the structures built up by plants, liberate the building stones and utilize them to build up the animal body.

WHEN NATURE OVERRULES HER OWN LAWS.

We always think of Nature as doing her work in an orderly and well-regulated manner. It is difficult to conceive of Mother Nature hurrying about her work. In guiding the building of an animal body nothing can lead Nature off her path, providing, of course, that the animal receive the proper building material. A rich diet will not bribe her; the animal may store up some fat, but its growth it cannot hasten.

If, however, an animal which is stunted for a given time, due to improper food, begins to receive a diet which is adequate, it will immediately begin to gain in weight and grow by leaps and bounds. Nature then will overrule her own laws of growth in order to help the animal gain what it had lost.

Rat 208, for instance, received a diet similar to that received by Rat 240, gliadin of wheat serving as the only protein. The animal was stunted for 40 days; then a part of the gliadin was replaced by casein of milk. This new protein supplied the building stones which gliadin lacked; the animal began to grow with unusual rapidity, and quickly gained what it had lost during the period it was stunted.

It is evident that Nature provided the cells of young animals with a far greater growing capacity than that which they normally make use of during their period of growth. Here we have still another of Nature's provisions for the well being of animals.

THE INORGANIC SALTS.

No phase in the diet of an animal has been overlooked as much as the rôle of the inorganic salts in it. They neither supply us with heat and work-energy (with the exception of calcium which goes to build bone) nor serve as material with which the body builds its tissues. Nevertheless, life is impossible without these salts. To remove the inorganic salts from a diet is more fatal to an animal than starving it. An animal which is able to live 00 days without food will not live half as long if its food is free from inorganic salts.

The inorganic salts seem to regulate the concentration of the fluids of the body. We know from experience to what extent our intestines become flushed when taking a saline cathartic. Fluids from all parts of the body rush to the intestine in order to dilute the concentrated salts and bring it in equilibrium with the other fluids of the body.

The inorganic salts are as important to the life of an animal as cement to the brick structure. Remove the cement and the structure can not stand. Remove the inorganic salts from our diet and life is impossible.

Mixed foods ordinarily contain sufficient inorganic salts to supply the needs of the animal body. The adding of table salt to our diets is, in most cases, the result of habit and not, as is the opinion of some, because the body actually requires the additional salt.

The white rats, being supplied with chemically isolated food materials, had to receive definite quantities of inorganic salts in their diets. After overcoming a number of difficulties our investigators furnished the inorganic salt requirements to these animals in a very novel fashion. They removed, by chemical processes the proteins carbohydrates and fats of milk, and left in it the inorganic salts. This fluid contained inorganic salts in the proportion in which Nature provided, and by adding it to the diet of these animals, it served the purpose excellently.

THE RÔLE OF BACTERIA IN NUTRITION.

The fear of germs has been so exaggerated in recent years that it is causing far more harm than the very bacteria which are most pathogenic. Indeed, the lowered resistance to disease which fear is sure to bring on will often make one susceptible to the bacterial diseases which he fears most. Of the countless bacteria which fill the air, water and soil, those that are known to bring on disease can be counted on our fingers, while the rest are busily engaged in enriching our soil, purifying our water, flavoring our foods and, in many other helpful fields of pursuit, being possessed with the single aim of making animal life possible.

We have known for some time that bacteria play an important part in the processes of digestion without, however, knowing definitely what this part is. Osborne and Mendel have shown specifically, in the course of their experiments, that bacteria exert a beneficial influence in the alimentary tract of animals.

The diet which they gave the rats, being chemically pure, was almost free from bacteria, and the animals under these conditions would often show signs of ill health. They thereupon decided to supply their animals with the proper bacterial flora. Their scheme was to add to the diet of their animals small quantities of excreta obtained from rats which were fed on regular mixed diets. Their rats thus obtaining intestinal bacteria of normal animals, showed marked improvement in practically every case.

To remove the possibility that there were other ingredients in the excreta, besides bacteria which brought about the beneficial effects, they killed the bacteria by sterilizing this material and fed it to the animals as they did before. The result was that the helpful effects were not in evidence.

That bacteria are helpful factors in digestion ought to be impressed very strongly, if for no other reason than to help allay the prevailing fear of these little bodies. The pathogenic germs can do us no harm unless they are given an opportunity to grow in our tissues, and this we virtually permit them to do whenever we lower our resistance by over-worry, fear, etc. In health, however, our bodies are sufficiently equipped to overcome the disease germs.

THE FATS.

We have spoken before of the importance of proteins, carbohydrates and inorganic salts in the foods of animals, to the extent that the removal of any of these from an animal's diet would cause the death of that animal. Whether or not fat is essential to the life of an animal has also been studied by these investigators.

They fed a number of animals with diets which were almost free from fats, and found that such diets did not interfere with the health of the animals. It would appear, therefore, that animals can grow and maintain good health for a time on a diet which is nearly free from fat.

This, it is readily seen, is only of scientific importance. In actual life it would not be advisable to eliminate fats from our diets on account of their relative cheapness and high heat value.

Osborne and Mendel have very recently carried out a series of experiments which have a more practical bearing. They tested the relative nutritive value of butter and lard. Butter, according to their experiments, is far more nourishing than lard. Animals which appeared weak and ill when getting lard in their diet showed marked improvement when butter was substituted.

At the present time these scientists are concerned in the study of the relative nutritive value of the various vegetable fats, such as olive oil, linseed oil, etc.

The experiments of Osborne and Mendel are known and discussed in every biological laboratory in this country and abroad. They have caused old theories to fall, and new theories to form. The science of nutrition is undergoing a period of reformation, and we feel not a little proud that two American scientists are among its reformers.

Recent Developments in X-Ray Tubes*

PROF. W. C. RÖNTGEN of Wurzburg, Bavaria, suspected that when a current of electricity passed through a glass tube containing a gas at very low pressure, invisible light waves were given off. The idea occurred to him that such rays might affect a flourescent screen in much the same manner as did ultra-violet rays. In order to cut out the visible light from his vacuum tube he wrapped it in heavy black paper. Upon operating the tube to make certain that the covering was completely light-tight, he noticed to his surprise that the fluorescent screen which he had left on the table three or four meters away glowed brightly.

Röntgen investigated the properties of the X-rays with characteristic German thoroughness. By 1897 he had amassed such a volume of information about X-rays that nearly every essential piece of research on their properties up to 1908 can be found in its more elementary form in his three original memoirs.

Röntgen's original tube of 1895 was, judged by modern standards, a pretty crude affair. The cathode was flat and emitted a diffused bundle of cathode rays which, upon hitting the glass at the far end of the tube, produced X-rays. In 1896 Campbell-Swinton added a platinum target upon which the cathode stream hit. This increased the penetrating ability of the rays obtained. In the same year Jackson made the cathode concave so as to focus the cathode stream upon a small area of the target. By giving more nearly a point source of X-rays this increased the clearness of radiographs for diagnostic purposes. The X-ray tube was soon changed in form, but not in principle. A device was added by which the pressure inside the tube could be increased at will, and various means were tried for removing heat from the focal spot of the target.

Meanwhile in 1912, Dr. Coolidge discovered the process of making ductile tungsten such as is used in the filaments of mazda lamps. Shortly after this discovery he became interested in perfecting a wrought tungsten target for X-ray tubes. During this work it became necessary to operate the tubes up to the limit of their capacity in order to find out how much abuse the tungsten targets would stand. During the course of this work he found that the ordinary aluminium cathode could be melted if sufficiently high currents were sent through the tube. He tried to remedy this by substituting a cathode made of tungsten whose melting point is very high. But such tubes were found to be very unstable. When current was sent through such a tube, the vacuum increased rapidly until finally no current would pass through the tube until gas had been liberated from the vacuum regulator. From a practical standpoint such a tube was hopelessly unsatisfactory. Finally it was found that if the process of operating the tube and immediately reducing the vacuum were repeated rapidly enough, the cathode became hot enough to glow, and that after this the tube would operate for several minutes at a time without it being necessary to let in fresh gas from the regulator. This suggested the idea of a cathode heated by some external means.

Richardson, and others in 1902, had shown that electrons could be obtained by merely heating the cathode, but had not been able to obtain constant results. Dr. Langmuir of the Research Laboratory of the General Electric Company, had shown that the rate of emission of electrons from a hot tungsten cathode in a very high vacuum depended only upon the temperature.

If we heat a tungsten filament, electrons are given off and soon a condition of saturation occurs around the filament. If the filament is made the cathode of a low-potential circuit, a small current passes. If the voltage is increased, a larger current passes. Finally a voltage is reached which sweeps away every electron as fast as it emerges from the hot tungsten. For all voltages above this, the current is constant, and is independent of the voltage. Thus we have a resistance as far removed from the ordinary Ohm's law resistance as possible. This is not because the conduction is carried on in any different way, but because the number of available electrons is limited. (The reason that Ohm's law holds in conduction through wires is that the supply of available electrons in the wire is practically unlimited.)

As a source of electrons in his tube, Dr. Coolidge made use of a small spiral of tungsten wire heated white hot from a storage battery in exactly the same way in which electric automobile lights are operated. This spiral is the cathode and a block of gas-free tungsten is the anode. The rate at which electrons are given off from the spiral depends upon its temperature, which is under the immediate control of the person operating the tube. The voltage across the tube is also controllable at will. As the voltage employed in ordinary X-ray work is much greater than is necessary to snatch all the electrons across from cathode to anode as fast as they are evaporated from the filament, even at the highest currents now in use in X-ray work, the voltage and current passing through the Coolidge tube are totally independent. Both may be adjusted to any desired value with any degree of precision desired, and at any such adjustment the X-ray performance of the tube can be duplicated time after time.

* Abstract of an address by Dr. W. D. Coolidge before the Edison Club, of Schenectady, and reported in the *General Electric Review*.

A Novel Engineering Expedient

OUT in Honolulu it became necessary recently to lower a large and heavy steel tank into a deep pit where there was very little space beyond the dimensions of the tank, so that the workmen had no room for ordinary blocking of the size required. The difficulty was met by building up a blocking of ice, and subsequently melting it out by steam.

The Cutlery Works of Thiers

Manufactures of the Old French Town Where Knives Have Been Made for Centuries

By Jacques Boyer

WITH its cutlery shops scattered along the water's brink on the right bank of the turbulent Durolles, Thiers is one of the most picturesque villages of France. Built one after the other at the bottom of the valley, these curious workshops, known throughout the district as "wheels," contain each some 6 to 12 grindstones, and in the course of a year thousands of knife-blades are sharpened in them. The workman, it should be said, labors as he pleases in these shops, as he is merely a tenant of the place he occupies in return for a rent of 80 to 100 francs a year to the owner of the "wheel." Thus, he preserves his liberty and comes when he sees fit to perform his severe task.

The operation of knife-grinding (in a primitive and painful but original fashion) is still carried out at Thiers. The grindstones revolve on a horizontal axle set a little above the river and the lower part of the stone dips into the water, which thus acts at the same time as a lubricator and cooler. The Durolle furnishes all the motive power for the entire workshops in which grinders are seen lying on their stomachs on planks. The plank, slightly inclined toward the workman, rests on a scaffolding, and its hardness is softened by a cushion or sheepskin. Keeping the head and shoulders up in the air, each man holds in his hands below the plank the piece of steel cut out by a punch from which he is to make a knife-blade by pressing it against the circumference of the grindstone. When it is necessary for the grinder to exercise considerable pressure, either to make the point or to thin a part where the metal is too thick, he raises himself slightly and presses the blade against the grindstone with all the weight of his body. On account, however, of the humidity prevalent in the "wheels," the poor fellow stretched at full length is easily benumbed and ends by being very rheumatic.

To avoid these ailments, therefore, as much as possible and to keep themselves from getting cold, the grinders use little dogs as "furnaces."

When ready to begin work each one of them whistles. Immediately a faithful little dog, trained to this task, comes to roll himself up on the crossed legs of the grinder. The intelligent animal covers its master's legs as much as possible, and at times stretches itself upon the grinder's back; in this way it communicates a gentle heat to him without which the lack of movement would cause the master to become chilled in a short time. The poor animals seldom live to grow old. After having filled for several years the office of a living "footstove" they become crippled, are killed to save them from useless suffering, and are replaced by another spaniel or nameless mongrel.

As early as the thirteenth century the "*coutelliers*" (old French for cutlers) were carrying on their work in the old Auvergnat town of Thiers, but the first authentic documents discovered by the archeologist Gustave Saint-Joanny only go back to the end of the fifteenth century. These papers are, first, a pardon granted in the month of October, 1460, by King Charles VII to a cutler of Thiers, Jehan d'Urson, who had compromised himself by making the molds used by a Parisian goldsmith named Faurel to turn out base money at the chateau of Saint-Cirques near Issoire. Then, a fragment of the land-book of the barony of Thiers, dated 1474, shows that a fourth of the population was at that time engaged in the cutlery trade. The industrial activity of Thiers began about this epoch, as did also that of Sheffield, and the town developed into an important cutlery center; this importance continued until the eighteenth century, when the industry began to decline. However, the knife popularly called *eustache* was still manufactured in Auvergne and excited the admiration of [illegible] at the exposition of [illegible]. The

Museum of the Louvre has a genuine example of this knife with a blade closing without a spring; on the one side of its wooden handle is the word "veritable" (genuine) and on the other "Eustache Dubois," name of its maker in Thiers. The expression *eustache de bois* (wooden eustache), generally used in France to designate this kind of knife, is therefore incorrect.
